POLK-1106745-168-RP298

the balance are made clear, and this is as true of such matters as professional freedom and loyalty as it is of voluntary action or the limitations which political parties must accept in a democratic State. Discussion, he reiterates, is the vital process of the life of any organized community, and those actions which abolish discussion destroy also the common life.

There could not well be a better corrective to some of the thinking and actions that in the past decade have so impoverished public life and threatened the integrity of our institutions, scientific and technical as well as others. These wise words on the importance of timing, and Sir Ernest's appreciation of the value of the voluntary agencies in respect of variety and spontaneity, are accompanied by full appreciation of the need for organized political parties in order that parliamentary government may function. He sets these, however, in the context of the society which the State should serve, and he invokes his principles of liberty, of equality—as distinct from uniformity—and of fraternity, not as isolated themes, but to be reconciled with each other and set in the context of a dynamic view of justice, joining and fitting together principles as well as persons. Here may well be found that stimulus to the creative thought about institutions which should help us to ask and to answer those vital questions about power and responsibility—the extent of the activities of the State, the reconciliation of State activity with enterprise and initiative, the desirable extent of equality of income, property or opportunity and the means for achieving them with least detriment to spiritual values—to which Lord Radcliffe also directs us. Above all, it should set us to that task of the general understanding and revaluation of character, ideas and institutions, as well as of thinking, which alone can avert the greatest danger to which Lord Radcliffe points, namely, the danger of losing our character, which is often superb, and being left with our institutions, which are sometimes inept. At the least, both Sir Ernest Barker and Lord Radcliffe make manifest the richness and greatness of our heritage and the relevance to our present problems of the aphorisms of Mill, Bagehot, Matthew Arnold and many others.

MATHEMATICAL SOCIOLOGY?

Mathematical Biology of Social Behavior

By Nicolas Rashevsky. Pp. xii+256. (Chicago: University of Chicago Press; London: Cambridge University Press, 1951.) 37*s*. 6*d*. net.

IT is claimed on the dust jacket of this book that "[it] comes as a challenge to quantitative social science. In great part the quantitative work of the social scientists has been of a purely empirical nature: measurable quantities were measured, and their quantitative relations described. While this approach unquestionably aids our knowledge of social facts, it does not provide a way to discover which relations are expressive of deeper realities and which are merely incidental. Professor Rashevsky proceeds otherwise. He starts with postulates concerning the behaviour and interaction of individuals among themselves and with their environment. . . . The 'large' social phenomena (emergence of classes, urbanization, social change, revolution) then emerge as *derived* mathematical formulations. . . . Hence a new dimension is added to social research".

Prof. N. Rashevsky, who holds the chair of mathematical biology in the University of Chicago, has written extensively on mathematical biophysics and is the author of a mathematical theory explaining mathematically certain physiological phenomena of the central nervous system. I am not competent to judge the value and significance of that work; but Prof. Rashevsky evidently believes that his discoveries in that field have an important bearing on the social sciences. The present volume therefore starts with a summary of some of his results and proceeds in a series of chapters to consider some of the "'large' social phenomena". The general procedure is to lay down certain postulates about human behaviour or about the association between certain variables, and then to draw conclusions from these postulates using mathematical methods of argument.

It is difficult to see what is gained by this approach. Prof. Rashevsky almost appears to believe that the use of mathematical methods in argument is an end in itself, for in his foreword he pleads as a point in his own favour that "the author actually uses mathematics everywhere, and does not merely talk about using it". Now it need scarcely be said that, in certain circumstances, mathematics may be helpful in making argument exact and in being conducive to clarity of thought. But if the results of mathematical manipulations claim to be of use in the explanation of phenomena observed in the real world, they should be verifiable empirically. It is not enough to claim that certain relations could be verified ***in principle***, as is done on several occasions in this book, particularly as the problem of measurement in the social sciences presents serious difficulties of its own.

Two results may be quoted in illustration. On p. 69 it is stated "that if the distribution of any innate ability which may affect social status is uniform, the social status will be distributed non-uniformly, as long as either one or both of the following conditions hold: the social status affects the probability of social encounters, or the probability of an individual's travelling a certain social distance is a function of that distance". This appears to assume in the first instance that social status is in some way influenced by innate ability, an assumption which is not immediately obvious and which in many societies may well be false. Moreover, social status itself is not defined; it is merely stated that the units measuring it will be chosen so that the measure lies within a certain interval. Social distance is apparently the difference between two social statuses and seems by implication to be treated as a continuous variable. Nowhere does Prof. Rashevsky consider whether it is really possible to regard social status as a unidimensional variable—that appears to be regarded as self-evident; nor does he show any signs of being aware of the difficulties that have been encountered in attempting to make this term more precise. His conclusion, which undoubtedly is a logical consequence of his assumptions, is quite unverifiable, and his assumptions are far from being universally true.

Again, we read on p. 231 that "if in any country the inequality $U(\bar{x},a,\beta,\varphi_0) > H$ becomes satisfied and if the condition of political restrictions is satisfied, then a revolution will occur and will not be prevented by jailing either eleven or eleven hundred communists". Three of the parameters entering into the inequality are what Rashevsky calls "psychobiological" ones; and although he claims that their averages and distribution function can *in principle* be determined experimentally, he does not enlarge on this statement, which seems to be unfounded. Thus φ_0 is a threshold above which an individual will be willing to apply force to improve his social conditions. It is not clear how the average value of this threshold can be obtained, nor even in what units it is measured. For all its air of mathematical precision, when the conclusion is shorn of its mathematical trappings it seems to mean that, if in a society there are sufficiently many people who are willing to apply a sufficient degree of force to improve their social conditions, a revolution will occur. In this form, the conclusion is not very profound and scarcely novel.

I do not think it is unfair to quote these two examples as representative, and I believe that, even though some of the results are not inherently unreasonable, the usefulness of the mathematical treatment is strictly limited. Social theorists who wish to explain what Prof. Rashevsky calls the "'large' social phenomena" can attempt to do so without the elaborate mathematical apparatus adduced here. Empirical sociologists, on the other hand, will at present have to content themselves with measuring what is measurable, thus adding slowly and laboriously to our still woefully inadequate knowledge of social facts, and in trying to improve their techniques of measurement. This may be rather pedestrian in comparison with an explanation of the "deeper realities", but is likely to be more fruitful in the long run.

E. GREBENIK

TREATISE ON INDUSTRIAL CHEMISTRY

Traité de chimie industrielle

Par Paul Baud. Quatrième édition, revue et complétée. Tome 1: Grande industrie chimique; problème de l'eau. Pp. ix+865. 5000 francs. Tome 2: Métalloides et métaux. Pp. vii+1053. 5800 francs. Tome 3: Industries organiques. Pp. vii+1148. 6800 francs. (Paris: Masson et Cie., 1951.)

M. PAUL BAUD has undertaken a stupendous task in writing, apparently unaided by any collaboration, these three volumes—a task to be measured not solely by the number of pages of closely printed matter but also by the highly diversified nature of the contents.

In Vol. 1 the production of common salt, the mineral acids, ammonia and other products based on nitrogen, the alkalis, fertilizers—natural and synthetic—receive very full treatment, and this volume closes with a chapter on water, its treatment for industrial uses and the production of potable water. Attention is focused on the many sources of contamination which can affect river water through trade effluents. The menace of river pollution is now well appreciated in most countries of western Europe and the United States because of its bearing on the problem of ensuring pure water supplies for drinking purposes.

About half this volume is taken up by consideration of solid fuels—wood, torbanite, lignite and coal, and their various distillation products. Low-temperature carbonization of coal and similar materials, the hydrogenation of coal—here some account is given of the Imperial Chemical Industries process at Billingham—and the high-temperature carbonization of coal for the production of coke and gas are well described, as likewise the German processes for utilizing brown coal, and shale retorting as practised in Scotland, Estonia and France.

The petroleum industry is considered very fully, attention being directed to the geology and distribution of the oil-bearing strata, the character of the different classes of natural petroleum now being won, followed by an account of the treatment of the crude oil and the various methods of refining adapted to the composition and character of the oil produced, in various parts of the world. Adsorption, thermal cracking and its rationale, with a brief description of the principal methods of cracking employed and the products resulting therefrom, receive adequate, if not always very full, treatment. Modern methods of refining are outlined, although, in describing the solvent method of treating wax-base oils, there is no mention of the use of furfural, now well established in the United States and Great Britain. Much attention has been paid to describing the Fischer–Tropsch and similar processes. This section of the book gives a full account of recent work on polymerization, dehydrogenation, isomerization and alkylation, all of importance in the development of any chemical industry having as its raw material hydrocarbons of the petroleum industry. Petrol, kerosene, white oil, paraffin wax, petroleum jelly, asphalt and pitch are described with full attention to properties and uses.

Vol. 2 embraces in its scope hydrogen, the halogens, the liquefaction of gases; oxygen, sulphur, phosphorus and their compounds; and industries based on silicon and carbon. In the part devoted to metals, the metallurgy of iron and steel is the longest and fullest section in the whole work and is well done, and particular note is made of the many types of high-duty steel alloys. But less space is devoted to a consideration of precious metals, the rare-earth metals and radioactive elements. Throughout this volume not much space is afforded to description of the salts of the various metals.

As is inevitable in a work of such scope, some chapters are far too brief and sketchy. The French have long been pre-eminent in the manufacture of fine soaps and perfumes, and it might have been expected that these two industries would have merited more detailed treatment in Vol. 3 than has been accorded them. But the chapters dealing with the industries based on cellulose, starch and sugar are well done, as likewise those on ethyl alcohol and on the fats and waxes. Dyestuffs, plastics and the rubber industries—natural and synthetic—and pharmaceuticals receive adequate treatment. But in the account of penicillin, no mention is made of the pioneering work of Fleming—a surprising omission.

As this is a work on industrial chemistry, its value would be enhanced by including in the appropriate places some up-to-date statistics showing production of raw materials and chemical products of world-wide importance. For example, it would be of great value to have some indication of present-day production of coal, coke, petroleum, the principal fatty oils and oil seeds, rubber and rosin, together with statistics showing world production of iron ore, steel, the principal metals and such important basic chemicals as common salt, natural and synthetic nitrates, caustic soda and sulphuric acid. The theoretical considerations underlying manufacturing processes are generally well treated, due attention being paid to physicochemical, thermochemical and thermodynamic relations—in many instances ably illustrated by appropriate diagrams.

There is much in these important volumes that the reviewer has not examined in detail, but even a cursory glance would reveal one outstanding defect —and it is indeed a serious one—a complete absence of documentation: there is not even a brief bibliography at the end of any chapter. Throughout these three thousand pages, though the names of investigators and of those prominent in chemical research and technology are mentioned in their appropriate places and with dates in many instances, chapter by chapter, nowhere is there a reference to any of their published papers or patents. It is hoped that the author may remedy this defect in any future edition. The addition of an author index would also be welcome: it might serve, during its compilation, to ensure more care in the spelling of proper names: some place names and authors' names, notably British and some American ones, are mis-spelled.

The volumes are copiously illustrated by nearly six hundred clear line-drawings, amply and carefully lettered, which greatly facilitate the reading of the text. It is a pleasure to record how well the volumes are printed and bound; despite the fact that the price to British readers will seem very high, the amount of matter available is of great value, though there is little information about developments of date later than 1947. H. M. LANGTON

EMBRYOLOGY AND EVOLUTION

Embryos and Ancestors

By G. R. de Beer. (Monographs on Animal Biology.) Revised edition. Pp. xii+160. (Oxford: Clarendon Press; London: Oxford University Press, 1951.) 15s. net.

OTHER than standard texts, there are few biological books that have enjoyed so long and fruitful a life as Dr. G. R. de Beer's "Embryos and Ancestors". It first appeared in 1930 under the title of "Embryology and Evolution", and ten years later, in expanded form, under its new title. The present volume is thus the third embellishment of Dr. de Beer's theme—that variation in the order and rate of appearance of structures in successive ontogenies (heterochrony) can have a considerable influence on phylogeny. Some new passages have been added to the original fifteen chapters of the book, and a smaller number of old ones deleted. There are four new chapters, of which the first three (on the evolution of the cœlenterates, on embryology and taxonomy, and on embryology and homology) are based on articles which Dr. de Beer has already published. The fourth, on the germ layers, is new.

Dr. de Beer cautions his reader that "it is characteristic of a slogan that it tends to be accepted uncritically and to die hard". Hence, he writes, schoolboys still incorrectly learn that during its life-history an animal "climbs up its family tree". His argument with the recapitulationists is, however, on a narrow issue; and, in his view, there would be no reason to disagree with them if only they "would abandon the assertion that that which is repeated is always the adult condition". Aware, therefore, that small matters can become the cause of much misunderstanding, he points out in his preface that, when he writes that pædomorphosis (by which he means the appearance or retention, in the adult stage of the ontogeny of a 'descendant', of a structure characteristic of the young stage of an ancestral animal) "has resulted in this, that, or the other", he is merely saving time and space—and not implying the operation of some peculiar process. Schoolboys and their masters do not, however, always read prefaces. There is, therefore, a danger that the view that major evolutionary changes are due to the operation of something called pædomorphosis, a thesis which Dr. de Beer expounds, may, in spite of his warning, also become a new slogan.

Nevertheless, this book will continue to serve the very useful purpose of introducing the student to an argument that not only has a long history but also practically a vocabulary of its own. Dr. de Beer writes with imagination, and what he provides launches the reader into an interesting and exciting field of biological thought. S. ZUCKERMAN

ANALYSIS BY DIFFUSION

Microdiffusion Analysis and Volumetric Error

By Prof. Edward J. Conway. Third revised edition. Pp. xxiv+391. (London: Crosby Lockwood and Son, Ltd., 1950.) 25s. net.

CONWAY'S influence on analytical chemistry has been twofold; it is a matter of temperament which one considers the more important. To some, in whose breasts the craft spirit still flutters, Conway's applications of his own elegant concept of microtitration in the Conway unit with the Conway burette are a permanent source of pleasure, whether in using or even in just contemplating them. The methods of micro-diffusion analysis have had, and are still having, a widening application; the main, if not the only, limitation to their usefulness is that the analysand must take part in the production of a diffusible compound that can be absorbed by a reagent in a closed system and that the change resulting from this absorption can be accurately measured. Examples of reactive substances measured in the Conway diffusion unit are ammonia, from Kjeldahl digestion or urea hydrolysis, alcohol in blood, carbon dioxide from sugar fermentation or carbonates and bicarbonates in body fluids, and a number of other substances not easily to be separated or isolated in small amounts with the precision required especially in biochemical analysis.

This third edition of what has now become an essential part of most analysts' libraries includes a number of new applications, for estimating carbon monoxide, lactic, acetic or other volatile fatty acids and chloroform in blood, as well as a modification of Winnick's method for alcohol in blood.

In spite of the combined æsthetic and practical appeals of the method, it has still not replaced all others for certain analyses in which its advantages seem overwhelming. Thus its use for routine estimations of urea, especially in places where potent vegetable sources of urease are easily available, make all other procedures deserve to become obsolete: it is at least as precise and as accurate as the best of them and is much less demanding of labour, that is, of time and attention. Yet only recently a biochemical journal published still another version of a micromethod, involving distillation after alkaline hydrolysis: the author probably never even considered, let alone tried out, the micro-diffusion technique.

It is in the science rather than in the art of volumetric analysis that Conway has made his other outstanding contribution to the practice of analytical chemistry, namely, in the study of error in volumetric titration, to which the book owes the second part of its title. It is the subject of some 115 pages—nearly one-third of the whole. In the opening eight chapters of the book there are 85 pages devoted to a discussion of the apparatus and principles used in micro-diffusion analysis; there also the author has much of value to say on various sources of error that still may go unrecognized.

Discussions of methodology thus occupy a large share of Conway's book—large, anyhow, relative to the space that analysts would have thought appropriate, say, twenty-five years ago. The influence of Conway on almost every branch of analytical chemistry is a tribute to the fundamental importance of—and the unseverable connexion between—his theory and practice; there are few authors that can have produced such wide effects with so few words in so short a time. The book's 376 pages (excluding references and index) appear modest indeed when compared with the great tomes (at correspondingly great prices) under which the scientist's shelves to-day increasingly groan. Maybe this is in part because the book first appeared only thirteen years ago and has not yet had time to swell unduly. More likely, it seems to me, it is an expression of the rare combination of modesty, logicality and singleness of purpose that caused the author originally to say no more and no less than was absolutely necessary, and to stick to that admirable procedure in both subsequent editions.

The production, printing, paper and binding of the book, its freedom from errors, the clarity of illustrations and graphs, all show an anxiety on the publisher's part to co-operate in the continued success of one of the outstanding scientific monographs of our day.

A. L. BACHARACH

FACTS AND SPECULATIONS ABOUT PROTEINS

Chemistry and Biology of Proteins

By Prof. Felix Haurowitz. Pp. xii+374. (New York: Academic Press, Inc., 1950.) 5.50 dollars.

THE appearance of a new text-book dealing with proteins is bound to be an occasion of great interest to students, teachers and research workers. Each previous effort to deal with this large field has been unsatisfactory in one respect or several, although, taken together, the existing text-books gave a useful synopsis of the literature down to about 1940. Prof. F. Haurowitz's book was written with graduate students in mind. Such students require from a text-book a connected account of a subject, with key references to monographs and reviews. This they will find. For specialists, too, there is a real mine of references here that will be useful to them, even if they can expect nothing of a comprehensive nature; and there are not many serious errors of substance.

Prof. Haurowitz shows, as those who have followed his experimental work will expect, a real feeling for the obligate relationship of the physical and chemical properties of proteins with their biological functions; the plan of the book reflects this feeling in an original way. After a short section on practical methods for extracting and handling proteins, the evidence is set forth on which modern ideas on the structure of proteins are based. Here an enormous amount of painstaking work by organic chemists is treated very cursorily; there is no reference to the discovery and structural elucidation of the amino-acids, nor to the synthesis and natural occurrence of peptides. On the other hand, much of the physical chemistry is given at considerable length. This is a pity, because previous text-books have shown a similar bias. This factual material is then reconsidered in a discussion on internal structure of globular proteins. The occurrence, properties and biological functions of the various proteins are then surveyed under the following heads: albumins, globulins and other soluble proteins; insoluble proteins (scleroproteins); conjugated proteins; proteins with enzymatic properties; proteins with hormone activity; role of proteins in immunological reactions; and toxins (toxic proteins). A short section is interpolated on the combination of proteins with other substances.

The next section deals with the supply of amino-acids for protein biosynthesis. Here, perhaps, more evidence would have been acceptable that free amino-acids are actual physiological building-stones for proteins. One feels, also, that too much emphasis, for a broadly biological work of this character, has here been placed on animals, to the exclusion of other organisms that are much more adept at synthesizing amino-acids and consequently of greater interest from this point of view.

The final section, on protein synthesis, is, as Prof. Haurowitz says, speculative. He is doubtful whether nucleic acids can have sufficient specificity to be critically determinant in reproduction. Here many will be with him; cytologists have always been uncritical in claiming importance for those substances that are easy to demonstrate. Prof. Haurowitz suggests that nucleic acids act as stretching agents for holding proteins oriented in a two-dimensional arrangement. Identical two-dimensional protein structures are synthesized on such templates, and then undergo three-dimensional folding which is determined by a variety of other cellular constituents. I find it much harder to picture a 'positive' protein template laying down on itself an identical series of amino-acid residues, as Prof. Haurowitz postulates, than to imagine successive positive–negative–positive interaction of a number of complementary structures as in photography and newspaper printing. Here, at least, we have good analogies from the study of immunology, while in analogy to the positive–positive complementarity Prof. Haurowitz quotes only such events as the crystallization of pure amino-acids from solutions of mixed amino-acids, events which are unusual in the experience of many workers. My feeling is that, as usual in biology, much current speculation will turn out to be gross oversimplification. To treat the 'template' idea as axiomatic is to overrun existing knowledge; it is by no means yet proved that amino-acids are built directly into large protein-like molecules without passing through a complicated series of intermediate stages.

Taking it as a whole, students will find this book a stimulating supplement to previous text-books, and research workers in all the fields that are concerned with proteins will find in it new and interesting ideas and references.

R. L. M. SYNGE

MYXOMATOSIS IN AUSTRALIA

A STEP TOWARDS THE BIOLOGICAL CONTROL OF THE RABBIT

By F. N. RATCLIFFE, K. MYERS, B. V. FENNESSY and J. H. CALABY

Wildlife Survey Section, Commonwealth Scientific and Industrial Research Organization, Canberra, Australia

A REMARKABLY interesting epizootic of the virus disease, myxomatosis, has developed during the past fifteen months in the wild rabbit population of south-eastern Australia[1]. Resulting from the natural spread, on a vast scale, of a deliberately introduced infection, we believe it to be an event without precedent, and the first indication of a pathogen working in the population of a mammal pest in a way that holds promise of achieving a degree of biological control.

After its appearance among laboratory rabbits in South America at the end of last century, and its description by Sanarelli[2], myxomatosis attracted considerable attention from research workers in both the New and the Old World. The mystery of its origin and epidemiology was not cleared up until 1942, however, when Dr. H. B. Aragão[3] showed that the reservoir of the disease was the native Brazilian "rabbit" (a species of *Sylvilagus*), that in this natural host of the virus the infection ran a mild and rather prolonged course, and that it was transmitted in the field by mosquitoes.

It was Dr. Aragão[4] who first suggested that myxomatosis might help to control the rabbit (*Oryctolagus cuniculus*) in Australia. The New South Wales Department of Agriculture obtained virus from him in 1926; and the results of the ensuing laboratory studies were reported by White[5]. The investigations carried out under the ægis of the Council for Scientific and Industrial Research (now the Commonwealth Scientific and Industrial Research Organization) were initiated at Cambridge in 1933 by Sir Charles Martin[6], and continued in Australia by Dr. L. B. Bull and his associates. One of their first concerns was the confirmation of the already fairly clear indication that the virus would be safe to liberate in the field. The virus is, of course, highly pathogenic to both the wild and domesticated forms of the European rabbit, the infection being almost invariably lethal. In contrast, all the common domesticated animals, representatives of the native fauna (mostly marsupials) and the introduced hare (*Lepus europaeus*) were found[7] to be refractory.

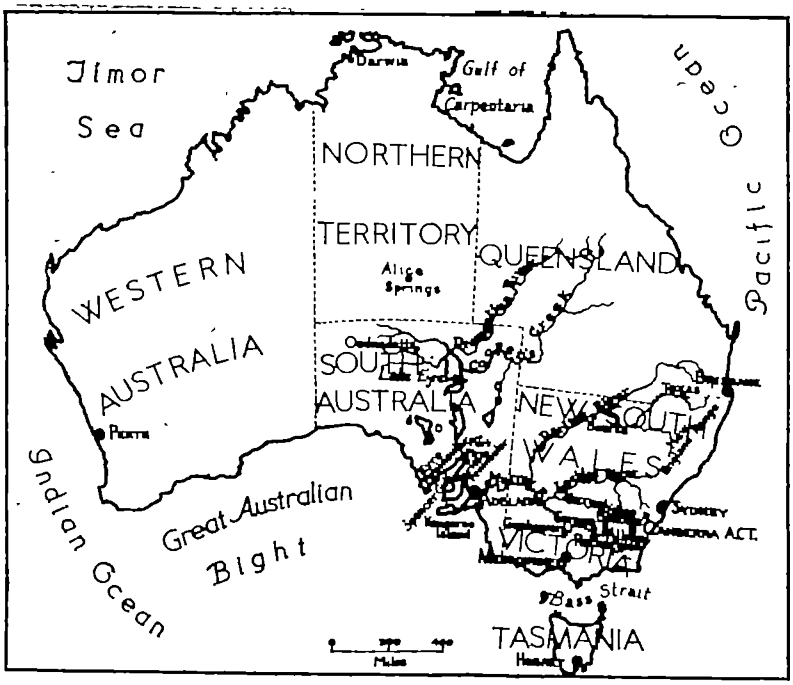
The results of the main Australian investigations have, unfortunately, only been published in summarized form[8]. At the time, it was not known that myxomatosis was essentially an insect-borne disease; but Aragão[9] had discovered that the cat flea (*Ctenocephalides felis*) could transmit the infection, and it was suspected by the Australian workers that insect vectors might assist the spread of myxomatosis in the field. Transmission by the insects considered most likely to be potential vectors in Australia (the stickfast flea, *Echidnophaga myrmecobii*, and mosquitoes) was therefore made the subject of special study in the laboratory. The flea and four species of mosquito were shown to be capable of acting as vectors. The investigations were concluded with a series of field trials, which had to be carried out in isolated localities in the semi-arid pastoral belt—fortunately the favoured habitat of *E. myrmecobii*. The results indicated that the flea transmitted myxomatosis under natural conditions, though its efficiency as a vector was limited by its restricted mobility. They also revealed the interesting fact that foxes, presumably by selective predation on lethargic infected rabbits, could prevent the establishment and spread of the disease. Although spread of the infection from one warren colony to another had occurred in an earlier experiment (carried out in a ninety-acre enclosure), there was no evidence of this taking place in any of the field trials in which the disease was established in unconfined rabbit populations.

A very serious rabbit situation developed in Australia in the years immediately following the War, and the newly established Wildlife Survey Section of the Commonwealth Scientific and Industrial Research Organization decided to re-examine the practical possibilities of myxomatosis. Following the lead of the earlier work, we planned first to carry out field trials in, among other places, areas where mosquitoes were likely to be prevalent. Between May and November 1950 seven liberations of the virus were made on five sites in the Murray Valley, four being in the Albury–Corowa area and one (the site of the earliest liberation) about a hundred miles downstream near the small town of Gunbower, Victoria.

The detail of the history of these trials is not relevant to subsequent events. All were disappointing in that, except in a portion of one of the experimental areas, the disease had no noticeable effect on the rabbit populations. Every site was kept under observation until the infection appeared to have died out, or at any rate had reached so low a level that weeks separated the sighting of sick individuals. By December, observations were concentrated on the two sites where the last (October and November) virus liberations had been made, one in the alpine foothills north-east of Albury, the other near Rutherglen in Victoria.

During the first week in December, myxomatosis flared up on the Balldale test site near Corowa, situated about seven miles north of the river in New South Wales. Almost at once reports began to come in of the appearance of the disease in other places, some on the Murray main stream, some on the northern tributaries. One of the earliest (December) outbreaks, disclosed in later surveys by a colleague, J. Brereton, was on the Darling River nearly four hundred miles from Corowa. There were other almost as surprising, but perhaps less well authenticated, early records.

The widespread dispersal of the virus, which with intensive local spread produced the remarkable epizootic that developed in the next two or three months, cannot be fully and satisfactorily explained, and probably never will be. One thing we believe to be beyond question: the spread of the disease was a reflexion of the movement of infected insects, almost certainly mosquitoes. The relative importance in the general mobility of the vector population of long and short flights, and perhaps the passive carriage on high-level winds, must remain a matter of conjecture. There is presumptive evidence, however, that long flights (or passive transport) were sometimes involved. Nothing else could very well explain the isolated outbreaks that occurred along the southern



margin of the epidemic area, for example, in the dry north-west of Victoria, and, in South Australia, at various points in the Adelaide Hills district, one on Yorke Peninsula, one near Port Pirie at the top of Spencer's Gulf, and one each on the east and west coasts of Eyre's Peninsula. These outbreaks were separated by distances of up to fifty miles. Even more isolated was the one discovered in September 1951 near Alice Springs in Central Australia.

An analysis of the December outbreak records points to the existence of an area, or areas, of disease activity, providing a source of infected insects, prior to the Balldale flare-up. We have failed to obtain direct evidence of such activity; and thus we can only record the possibility that one or more of our earlier and apparently abortive virus liberations may have contributed in some way to what might be termed the embryonic stage of the epizootic.

After the New Year, the epizootic gathered momentum rapidly. By mid-February 1951 myxomatosis had appeared in practically all parts of the huge area that was to be affected before the advent of winter, and the peak of the epizootic had passed in most districts. A feature of this phase that impressed observers was the speed with which the disease swept through local rabbit populations. When high mortalities (of the order of 90 per cent or better) occurred, they were as a rule achieved within 3–4 weeks of the date on which the infection was first noted in the population.

By the end of March a state of general quiescence had been reached; and on the results of our own and colleagues' surveys, and reports received through co-operating State Departments, it was possible to map the epizootic with reasonable accuracy. The most obvious feature of the resulting picture was the close association of the disease with rivers, creeks, irrigation systems and swamps, a clear indication of the paramount importance of water-breeding vectors. (We found that on Beadle's[16] vegetation map of the Western Division of New South Wales, the distribution of flood-zone plant associations delimited with remarkable accuracy the areas in which high rabbit mortalities had been achieved.) Outbreaks of the disease that had occurred in the 'dry' country had as a rule been transient and of low intensity.

The 'myxomatosis map' for the 1950–51 summer is completely dominated by the Murray–Darling system, along most branches of which the disease had spread. The distance, as the crow flies, between the Murray mouth in South Australia and the farthest point on the system reached by the epizootic (the Texas district on the Queensland – New South Wales border) is 860 miles. When one takes into account the coastal areas of New South Wales and Victoria (where State-organized campaigns of virus distribution succeeded in establishing the disease), the outbreaks in south-west Queensland and north-east South Australia extending around Lake Eyre to an area south of Oodnadatta, and the westward spread of the Eyre's Peninsula outbreak already referred to, we find myxomatosis dispersed over an area nearly a thousand miles from south to north, and some 1,100 miles from east to west. The collection of adequate and satisfactory data from so vast a territory presents very obvious difficulties; and the surveys which we, and colleagues in the Organization, have carried out over the greater part of it during the past year have of necessity often been rather superficial.

The marked differences in the performance of myxomatosis in different parts of the Murray–Darling system can be explained by the nature of the season. 1950 was a year of average or sub-average rainfall in Victoria; whereas the north-eastern half of New South Wales and most of Queensland received record-breaking precipitations, resulting in flooding on an almost unprecedented scale in the northern part of the epizootic area. The last flood rains occurred in November 1950; but their effects in the form of abundant surface water lingered for at least a couple of months.

Along the Murray main stream useful 'controlling' kills were confined to a very narrow strip, often only a few hundred yards wide (and usually corresponding closely to the *Eucalyptus camaldulensis* zone), except where irrigation complicated the picture. The same applied, in general along the Murrumbidgee. On the Lachlan, farther north, the high-mortality belt was wider, and we found river-fronting grazing properties tens of thousands of acres in area that had been swept virtually from fence to fence by the epizootic. It was, however, in the region lying east and north-east of Bourke on the Darling, with its dendritic development of tributary streams tapping the ranges of New England and south-eastern Queensland, that the most spectacular results were met with. Here the disease became emancipated, as it were, from the waterways as they appear on the map, and the epizootic developed areally. In places it was possible to drive for a day or more through country that had previously been swarming with rabbits and see only isolated survivors.

Two other features of this first phase of the epizootic deserve mention. In general, hills set a limit to the natural eastward spread, the disease rarely penetrating up the rivers beyond the points where they emerged on to the plains. Then there was evidence of the seasonal decrease in vector activity freezing, one might say, the epizootic at a stage when chance effects were still apparent. Areas of eminently favourable country, including substantial stretches of Murray frontage, were by-passed or only feebly invaded by the disease, the active advance of which was rather suddenly curtailed in certain places.

The results of the first, large-scale, impact of the myxoma virus on the wild rabbit population of Australia indicated that the disease would be of material assistance to man in his efforts to deal with the country's most serious animal pest, but also that it might have severe ecological limitations. Epizootics of myxomatosis could only be expected to occur where rabbits co-existed with the right types of insects in adequate abundance; while a usefully high mortality seemed likely to depend on vector densities that would be exceptional in many rabbit-infested areas. It was obvious that no sound assessment of the practical potentialities of myxomatosis could be made, nor could anyone decide how and to what extent the virus could be helped in action, until we knew a great deal more about the insects on which its performance depended.

When we started on our field experiments with myxomatosis, it was known that two species of fleas[6,7] and about half a dozen species of mosquitoes[8,9] could transmit the infection. Shortly after the epizootic got under way a colleague, R. Mykytowycz[11], demonstrated that the common and widely distributed *Culex annulirostris*, and also a species of *Simulium*, played a vector part on the Murray River flats; and later he showed, by laboratory experiments, that the rabbit louse (*Hæmodipsus ventricosus*) and a mite (*Cheletiella parasitivorax*) could act as vectors. The obvious conclusion (which was supported by the results of a laboratory study by Fenner, Day and Woodroofe[12]) was that transmission was mechanical, and that any blood-sucking arthropod that fed on more than one host individual during its lifetime was a potential myxomatosis vector. The relative efficiency of a vector species, and the importance of the role it would take in the epidemiology of the disease, would depend on its ecology and habits, including its mobility, the strength of its preference for the rabbit as a source of a blood meal, and the length of the period of its abundance.

It was clear that the scope of the vector field studies called for was extremely wide. Moreover, the Wildlife Survey Section was handicapped by the fact that practically no relevant information on the potential vector fauna was available—the mosquitoes had been well covered taxonomically, and that was virtually all that one could say.

During the 1950–51 summer it was possible to correlate the performance of myxomatosis in the Murray Valley with the distribution and activity of *Culex annulirostris*; and it seemed safe to conclude that this mosquito, which we found had a strong tendency to remain confined to timber cover close to its breeding-places, had been the principal vector in that area. Heavy rain in mid-February over part of the region produced dense populations of aedine mosquitoes, mainly *Aedes theobaldi* and *A. sagax*. (We planned to pay particular attention to these and other members of the genus that are opportunist exploiters of temporary surface water, and seemed to possess powers of dispersal above the ordinary; for they, among mosquitoes, offered the greatest hope of being able to spread myxomatosis widely and rapidly in country away from rivers and permanent swamps.) Some localized heightening of disease activity, with a spread beyond its earlier confines, pointed to transmission by these species. In view of our later observations, however, and the possibility that some more cryptic species might have been at work, the value of any deduction made at the time as to the vector efficiency of *Aedes theobaldi* and/or *sagax* is questionable.

The second (1951 winter) phase of the epizootic developed almost imperceptibly from the quiescence of autumn. Except in parts of southern Victoria, where a few sharp localized outbreaks occurred that might have been the result of winter mosquito activity (apparently a recognized feature of the coastal belt), this phase was typified by a widespread smouldering of the infection, much of it at such a low level of intensity that it almost escaped notice. In a few places an appreciable mortality was ultimately attained. There were very few winter sightings of sick rabbits in Queensland.

Though the reverse of spectacular, the behaviour of myxomatosis during the winter months was of great interest, and of equally great significance epidemiologically in that it provided a demonstration of the ability of the virus to persist, perhaps indefinitely, in the rabbit population.

Winter activity tended to follow one of two patterns and developed, to our surprise, almost exclusively in areas that had not been reached by the disease during the summer epizootic. (Thus surviving rabbit populations on river frontages, even if substantial, were rarely affected.) Some of the outbreaks were localized around swamps, hillside seepages, etc., suggesting that they had been initiated by wandering mosquitoes 'homing' to water. Others, more diffuse as a rule, showed a marked association with patches of tussock grasses and more particularly saffron thistles (*Carthamus lanatus*).

We were unable to obtain any indication of the identity of the vector or vectors responsible for winter transmission. Except for confirmation of the persistence and activity of mosquitoes (chiefly *Aedes camptorhynchus*) in parts of the Victorian coastal belt, our collections and observations in the outbreak areas were fruitless. We rather suspect that future investigations will reveal that the winter vectors of myxomatosis are ectoparasites.

The third (spring and 1951–52 summer) phase of the epizootic is still in progress at the time of writing. The abnormality of the season has made it, in one respect, disappointing. The lateness and partial failure of the monsoon left a substantial part of the epizootic area in the grip of a severe drought until close on the end of the summer, so we have not been able to obtain the information we had hoped for from Queensland and northern New South Wales.

In the extreme south, along the Victorian coast, the disease appeared on a number of offshore islands early in the spring, and some of the highest mortalities yet recorded were achieved. The species that seems most likely on our present knowledge to have played the main vector part in these outbreaks and in the early activity that developed in parts of coastal South Australia is *Aedes camptorhynchus*, the dominant mosquito of the region and a breeder by choice in brackish swamps.

As our surveys of mosquito breeding grounds had led us to expect, the season opened in the Murray Valley with a widespread emergence of *Aedes sagax* and *theobaldi*. The wave of abundance of these two species was not correlated with any marked general increase in disease activity, such as we were waiting for; and it may be said that a clear indication of the inefficiency of *A. sagax* and *A. theobaldi* as myxomatosis vectors in the field was one of the two most important things to come out of the season's observations—the other being the subsequent demonstration of the vector role of *Anopheles annulipes*.

The surroundings of a lake halfway between the Murray and Murrumbidgee Rivers, selected by one of us (K. M.) as a special study area, provided the stage for a sequence of events that miniatured the large-scale developments which occurred from late November on. The infection was artificially established and maintained in the dense local rabbit population throughout the period of abundance and dominance of Aedines, during which the situation remained static. A dramatic change occurred, however, when *Anopheles annulipes* (accompanied, in lesser numbers, by an unnamed but now well-known species of *Culex*) began to be prevalent; and a very active epizootic was soon under way.

It had been observed that *Aedes sagax* and *theobaldi* attacked stock (especially cattle) in marked preference to rabbits, which might well be the key to their inefficiency as vectors. The fact that *A. annulipes* was feeding on infected rabbits was established by inoculating suspensions of random-caught insects into healthy animals; and some interesting and significant observations were made on its habits. First, it was found to harbour during the daytime in rabbit warrens, as did the *Culex*. (Later, we obtained evidence in another locality that suggested penetration for a considerable distance underground.) Then it was noted that when the rabbits in one section of the area had been virtually exterminated, and the warrens fell into disuse, Anophelines appeared in increasing numbers in the burrows on a well-populated sandhill not far away, where the disease spread quickly. Similar behaviour was observed on other study areas.

The main summer epizootic developed over a vast, roughly crescent-shaped area, extending from the mouth of the Murray in South Australia eastward and then northward, inland of the Great Divide. It covered a substantial part of Victoria (including the south-west coast) and the southern two-thirds of the broad belt of undulating country lying between the mountains and the plains in New South Wales; while there were scattered outbreaks in the highland valleys along its eastern margin. In some regions, notably the Murray Valley, the epizootic built on, and extended, the effects of the previous summer's activity; but for the most part it developed in country that had not been reached by the disease during the first phase of its spread. It is difficult to estimate the relative importance of natural and artificial dissemination of the virus in preparing the way for the second summer epizootic. Winter and spring sightings of sick rabbits had been reported in many, if not most, parts of the affected area; but the State-sponsored inoculation campaigns must have resulted in a more thorough and widespread 'seeding' of the infection than would have been achieved naturally.

We believe that the principal vector in the 1951–52 summer epizootic was *Anopheles annulipes*. Its presence, as revealed by the discovery of adults in the warrens or local breeding, has been the one vector factor common to all those parts of the affected area in which we have been able to make adequate and timely observations. The intensity of disease activity has, in general, been correlated with the distribution of suitable *annulipes* breeding grounds—vegetated swamps, the weedy margins of slow-moving creeks, and waterholes formed by the drying up of hill streams. *A. annulipes* breeds with *Culex annulirostris* in the lagoons of the Murray flats, but it is a much more adaptable and far-ranging species than the latter. *C. annulirostris* probably played a vector part during the summer just passed, in the zone where it occurred; but the indications are that it was forestalled in time and outstripped in range by the Anopheline. Along the Murray, in 1951–52, where conditions made the comparison possible, a useful rabbit kill extended for almost as many miles back from the breeding waters as it did hundreds of yards during the previous summer's epizootic.

During this last phase of myxomatosis activity, high local mortalities were sometimes attained with the rapidity that characterized the 1950–51 summer epizootic; but in several areas the disease worked unobtrusively for two or three months to effect a comparable reduction in the rabbit population density.

In this perforce somewhat oversimplified account of the course of the myxomatosis epizootic from December 1950 to April 1952, it has been impossible to mention many interesting and often puzzling local outbreaks in which vectors other than mosquitoes seem to have been involved. (Discussion of these must await the full report of our field studies.) Our observations have admittedly been deficient in the outlying parts of the epizootic area, and on the eastern seaboard and highlands; and the picture we have presented above reflects this fact. Our main and most intensive investigations have been carried out in northern Victoria and southern New South Wales, where mosquitoes are undoubtedly the most important myxomatosis vectors. In this region our observations now cover the full cycle of the seasons, and the broad pattern of the ecology of the mosquito fauna is now becoming clear, with its succession of species attaining dominance as larval and adult habitats change in nature and extent. The important point is that the course of the epizootic in the Murray Valley can be very satisfactorily explained by the entomological picture that has been disclosed; and we feel that the information gained in this region will be broadly applicable to other areas in which the same species of mosquito occur.

It is clearly necessary to try to answer two questions that are inevitably being asked: What has been the overall effect of the epizootic to date on the rabbit population, and what long-term contribution to a solution of Australia's rabbit problem can we now expect from myxomatosis? Unfortunately, it is not possible to answer either of these questions confidently and satisfactorily.

We have considered most carefully ways and means of giving quantitative expression to our estimate of the efficacy of the epizootic, but have reluctantly abandoned it as impracticable. While we might hazard the guess—which would not be a 'blind' one—that an average overall reduction in the rabbit population of the order of 50 per cent had been achieved in those districts where the disease had been active, such a statement would be of little value without a quantitative definition and estimate of the areas in question, and this cannot be given. (Appreciation of the vastness of the region involved, and the impossibility of acquiring detailed knowledge of more than an insignificant fraction of it, should make this point self-evident.) A tentative estimate that myxomatosis had been active, that is, had caused an appreciable mortality, in one-fifth of the rabbit-infested country of Victoria, and one-tenth to one-eighth in New South Wales, might be very wide of the mark.

The epizootic, especially during the recent summer, was observed to work more effectively in heavily infested spots, thus "levelling out the peaks" of the variable regional population. One survey, of a sample area of a hundred square miles (64,000 acres) between the Murray and Murrumbidgee Rivers near Albury, revealed that while 20,000 acres were classed as heavily rabbit infested before the epizootic, only 640 acres remained so immediately after it. There are substantial tracts of land in south-eastern South Australia, Victoria, and New South Wales over which rabbit density has been reduced to a very low level, as little as, or even less than, one-tenth of the 1950 figure. Many landholders (perhaps to be numbered in thousands rather than hundreds) have had their personal rabbit problems virtually solved for the time being by myxomatosis; and immediate obvious benefit in the form of increased pasture growth and stock-carrying capacity has been reported from a number of districts.

Our observations indicate that there has been no substantial recovery of the hardest-hit rabbit populations as a result of breeding; but this may be explicable to some extent by the seasonal conditions. In parts of the epizootic area, for example, in Queensland, rabbits reappeared 4–8 weeks after disease activity had ceased, necessitating a reduction in the original, very high, estimate of regional mortality. We can offer no explanation of this temporary disappearance of most of the surviving population.

The epizootic took place at a time when rabbit numbers were generally high; and the area affected included much of Australia's most heavily infested country. With this in mind, and a knowledge of the statistics of the skin and carcase trade, we would say that the rabbits killed by myxomatosis in the period under review could be numbered in tens of millions (rather than in millions—certainly not in hundreds of millions). This estimate is given merely as a matter of general interest. It provides no indication of the 'control value' of the epizootic: no figure for a short-term mortality could do this.

One thing that makes it difficult to assess, on the basis of our analysis of the current epizootic, the importance of the part that myxomatosis will play in the control of the rabbit in Australia is the fact that the 1950–51 and 1951–52 seasons have both been somewhat abnormal. The former provided exceptionally favourable conditions for transmission in northern New South Wales and Queensland; and while the following summer was definitely unfavourable in the north, we are inclined to believe—though this conclusion needs to be checked by future observations—that dry, but not too dry, conditions in the south may have resulted in an unusually widespread prevalence of *Anopheles annulipes*. (For this vector to breed prolifically in the belt of undulating country that benefited most in the 1951–52 epizootic, the spring-fed creeks must be maintained in the right condition for a reasonable period of time, free from flushing on one hand and too great a degree of drying-out on the other.) Another fact that has to be taken into account is that the virus of myxomatosis is still in what might be termed the colonizing stage, and that the future should see it more widely—and at the same time more uniformly—distributed through the rabbit population, and hence better able to take advantage of local conditions favouring rapid transmission.

It is now reasonably certain that myxomatosis will be permanently established as an enzootic infection in the wild rabbit population of Australia. Its long-term overall effects will depend on something more than the summation in space and time of local mortalities. For example, the extent to which rabbits tend to concentrate in, and repopulate by immigration, well-watered country, and the effect of the disease on the development of normal breeding behaviour—two things about which we know next to nothing—may be of critical importance.

Apart from those just given, there is one very cogent reason for hesitating to estimate the future potentialities of myxomatosis. The possible effect of the natural process of mutual adjustment between parasite and host—the myxoma virus and the rabbit—cannot be ignored. The questions involved in this aspect of the myxomatosis problem lie in the specialized fields of the virologist and the geneticist; and they are receiving attention at the present time from Prof. Frank Fenner, of the Australian National University, and others. A close watch is being kept for evidence of changes in the virulence of the virus; and the likelihood of the susceptible rabbit population being replaced, within a period of years rather than decades or centuries, by one possessing a significant degree of resistance to the infection is being examined. Our observations suggest that recoveries in the field have been more frequent than the laboratory indication of virtually 100 per cent lethality would lead one to expect. If recovery is shown to have a genetic basis, the acquisition of some degree of resistance by the Australian wild rabbit population must be regarded as inevitable.

Too many people for individual mention—colleagues in the Organization, officers of State Departments, and landholders in the epizootic area—have helped us in our work. A detailed account of our investigations is being prepared for publication, in due course, as a C.S.I.R.O. Bulletin or in one of the Australian scientific journals. It remains only to record that the enthusiastic and persistent advocacy by a Melbourne specialist in virus diseases, Dame Jean Macnamara, was a material factor in the decision to initiate experiments with myxomatosis in 1933, and to resume field studies in 1950.

ALCHEMICAL ILLUSTRATIONS*

By Dr. F. SHERWOOD TAYLOR
Director of the Science Museum, London

THE ideas and practice of alchemy are to-day so foreign to the mind of the age that, contrary to our custom, we have felt the need to preface the exhibition of "A Hundred Alchemical Books" by some thoughts about the nature of the art and the character of the illustrations that purport to explain it.

How, then, does alchemy differ from chemistry? On what grounds do we call this book alchemical and that book chemical? As in all distinctions of real things, the line of demarcation is not quite sharp; but the principal difference of alchemy and chemistry is to be found in their purpose. Alchemy was a practical art purporting to make gold from base metals or to perform some other master-work of perfecting some created thing in its own nature: chemistry is a science directed to the investigation of the nature and properties of all kinds of matter. One is a work to be done: the other understanding to be gained.

There are other, though less-essential, differences. Alchemy looked backward. There were great men in the past who had done the work, known the secret and concealed it in their books: the task of the alchemist was to penetrate these cryptic repositories of knowledge, a task of reflexion rather than experiment. Chemistry looks forward, honouring the men of the past, but seeking knowledge never yet in the mind of man, through the process of reasoning and experiment.

Alchemy was a lonely work, to be done and completed by a single worker for his own ends. Were the work once done, the laboratory and its manual tasks would be abandoned and the alchemist would lead a new enlightened life, of which we are told but little.

Chemistry is cumulative, the work of hundreds of thousands, sharing and transmitting the knowledge they gain: it is never-ending, for every research opens the way to more. In all this may be seen the resemblance of alchemy to an art, rather than a science.

Yet alchemy was one of the contributors to chemistry. The very idea of chemistry was unknown until the early sixteenth century. There was a theory of matter, there was alchemy, there was a diversity of practical arts which we should to-day regard as within the field of the chemist, but that all these should be treated as kindred subjects concerned with the transformation of matter was the idea of Paracelsus, who sought to group them together under the name of 'alchemy'. For him alchemy was the way the stomach concocted the food and the doctor prepared the medicine; the smelting of iron was alchemy, as was also what was done by the baker, the cook and even the stoker. In all this we see the ideas of separating the pure from the impure, and the transforming of matter. Nearly a century later Andreas Libavius took the name Alchemia for what we would call the first general text-book of chemistry. Thus in the seventeenth century alchemy had at first the double meaning of the gold-maker's art and the science of chemistry: only gradually was 'Alchemia' reserved to the first and 'Chemia' to the second. Gradually through this century the subjects became separated. Alchemy became ever less chemical and more symbolic, while chemistry relinquished, first its interest, then its belief in the alchemical process.

Alchemy gave more to chemistry than a name. The first chemical laboratory, perhaps the first laboratory, was an alchemical laboratory, and practically all the apparatus used before the period of the study of gases was invented by alchemists, and can be seen illustrated in the books on alchemy.

The ideas of alchemy as expressed in the alchemical works are a tangled web of notions drawn from science, philosophy and religion, but in them it is possible to see a certain broad pattern. That metals were to be transmuted into gold was an idea made acceptable by its promise of release from poverty: that metals could be so transmuted was made credible by the Aristotelian theory of matter, which allowed the possibility of every element being changed to every other. The works of Aristotle also put forward the theory that all metals were compounded in the earth of two exhalations, a moist and a smoky. What Nature could do in the rocks, the alchemist might hope to bring about in his vessels. The idea of these exhalations was akin to that of the all-pervading *pneuma*, spirit or world-soul, which in the Hermetic and Stoic philosophies was at once the material of all things and agent of all changes, operated by the ever-changing influence of the heavenly bodies.

This was the fundamental idea of alchemy: to gather the active spirit (the philosopher's mercury) and make it operate the change of one metal into another. But how to gather it? Somewhere, before about A.D. 100, the process of distillation was invented and provided the means of apparently drawing the volatile active part of bodies—the spirit—out of a great many natural bodies, and in the liquors so obtained were the hopes of the alchemists. From the first century to the eighteenth century they distilled and worked with every volatile body that they knew. Mercury and sulphur were favourites, and known before the accepted date of the beginning of Western alchemy: arsenic trioxide, ammonia, alcohol, the mineral acids were probably alchemical discoveries. Dew was a magical material for them, the direct product of the heavens, and they also distilled every conceivable plant and animal material in search of their 'philosophers' mercury'.

At some time, perhaps during the period of study of alchemy by the Arabs, there arose the idea of a 'medicine' or 'powder', a small dose of which, added to a molten base metal, would transform it into gold. This idea rapidly gained strength in medieval Europe, and a standard process for transmutation was gradually evolved. The philosopher's mercury was to be gathered in some fashion—and this was the secret most sedulously guarded. It was to be set in a sealed vessel with a little gold and silver, often made more mysterious and unattainable by being described as 'our' gold and 'our' silver, and subjected to gentle heat. The gold and silver were depicted as dissolving and 'marrying', forming a double being that died and was corrupted to a black mass, then was revivified, passing through glorious colours to the white stone that transmuted to silver, and by a repetition of the process to the red stone that transmuted to gold, and indeed would perfect every creature in its own kind. It is of little use to try to find a modern chemical equivalent of these supposed changes, for no chemicals to which the alchemists had access could have produced any of these effects. We may be sure that they did seal up various things and subject them to heat, causing changes which they observed. The more fruitful way of looking at the problem is to ask why they *expected* such changes and why they symbolized them as they did.

---

* Substance of an address given at the opening of an Exhibition of Alchemical Books at the Science Museum, London (*Nature*, 169, 1041, June 21, 1952).

What did a chemical change mean to the men of the Middle Ages ? It was essentially a generation of a new body and was thought of in terms appropriate to generation. There must be a marriage : gold must generate the seed of gold ; so gold, symbolized by the sun, must marry silver, symbolized by the moon. The character of the body produced in any generation was determined by the heavenly influences : the mercury of the philosophers was the physical condensation of those influences. The product was a seed · the seed must die in the ground, as the scripture tells, and from its black and putrefied remains springs the new being, the glorious body of the stone. The myth, if we may so call it, combines the two most potent ideas of man—the idea of marriage and the idea of resurrection and renewal. Is it surprising that the process fired the imagination of the artists ?

But why understand a physical process in such terms ? Man always desires to understand what he sees or conceives under some visual analogy. We have the atomic theory and conceive our chemical changes as the rebuilding of a structure. With a continuous theory of matter no such picture could be formed, and the human and spiritually oriented philosophers of the Middle Ages saw the chemical change under the analogy of the life of man. Man is generated and born, he dies to sin and is born again, he dies physically and is resurrected ; these transformations were what the medieval alchemist expected to see and supposed that he saw in chemical change.

Moreover, by a very characteristic reversal, the alchemists first constructed their view of chemical change on the analogy of man, and in later ages viewed man under the analogy of chemical change. Thus in the later years of alchemy, certain writers, notably Jacob Boehme, symbolized the mystical progress of man by the process of alchemy. The result is a fascinating equilibrium of chemical and mystical ideas, displaying a thousand shifting aspects to be exploited by the writer and his artists. Thus we expect and find in alchemical illustration not only figures of laboratory apparatus, but also every symbol that has a bearing on the ideas of transformation, marriage, generation, death, growth and renewal.

Both representational and symbolic illustrations are found in the alchemical manuscripts written in Greek, the texts in which were mostly written between A.D. 100 and 700. The Arabic manuscripts are, to my somewhat slender knowledge, but scantily illustrated, but certainly contain both elements. The elaborate series of symbolic pictures occurred in medieval manuscripts before they found their way into printed books, and it would seem that the more elaborate did not appear before the fifteenth century.

Printed alchemical books appear from the beginning of the sixteenth century. The first are distillation books, chiefly pharmaceutical, with alchemy taking a minor part. Some of these, such as the magnificent works of Brunschwyg, are illustrated by very fine woodcuts of a representational character. Symbolic alchemical works illustrated by woodcuts appeared at intervals throughout the sixteenth century ; but it is in the early seventeenth century that these attain their zenith. About the year 1625 there issued from the presses of De Bry and of Lucas Jennis a stream of finely printed alchemical books, adorned with finely conceived and beautifully executed engravings. As the seventeenth century proceeded, alchemy and chemistry achieved their separation. Chemical works with good plain pictures of apparatus abounded, though these commonly retained some alchemical matter and often a symbolic frontispiece. By the close of the seventeenth century, alchemical illustrations had disappeared from chemical textbooks, while the alchemical works, still produced in great numbers, displayed more of the influence of Rosicrucianism, the Cabala and Free-masonry.

We learn a not insignificant part of the history of chemistry by studying alchemy and its pictures ; also our eyes are opened to a view of the world other than the modern scientific—a view which we may regard as a horrifying example of unscientific thinking or as the addition of a poetic and human quality to our outlook on material things. Moreover, we learn something about man, his eternal problems and aspirations, and the manner in which desires and ideology affect his very observations, let alone the interpretation he gives them. We cannot view the scientific way of thinking truly except by a contrast with non-scientific thinking about the same subjects, a contrast for which the Exhibition now at the Science Museum provides material.

OBITUARIES

Sir James Irvine, K.B.E., F.R.S.

With the death, on June 12, of Sir James Irvine, principal and vice-chancellor of the University of St. Andrews, this ancient seat of learning mourns the loss of an illustrious son whose career at St. Andrews extended over a period of fifty-seven years in the successive capacities of student, lecturer, professor and principal. His services to the University, particularly during his tenure of the highest office for more than thirty years, can truthfully be described as inestimable. In that period he changed the face of the University and brought prosperity and high prestige to a time-honoured academic foundation which in his early days was marked by poverty, a paucity of students, and a lack of proper buildings and equipment for the teaching of science.

James Colquhoun Irvine was born at Glasgow on May 9, 1877. After his early education at Allan Glen's School and the Royal Technical College, Glasgow, he entered the University of St. Andrews in 1895 and graduated B.Sc. in 1898. Here he became a brilliant disciple of Thomas Purdie, professor of chemistry, who always remained in his memory. It was during an ensuing period of study under Wislicenus at Leipzig that he conceived the novel idea of applying Purdie's method of methylation to the investigation of the molecular structure of carbohydrates. From this idea sprang the famous carbohydrate research school at St. Andrews, which he developed with so much energy and success during his tenure of the chair of chemistry from Purdie's retirement in 1909 until his own appointment, in 1921, as principal of the University. These pioneer researches led to later work of the first importance in carbohydrate chemistry, much of which was carried out at Birmingham under the direction of Sir Norman

Haworth, who had formerly held an appointment in Irvine's department at St. Andrews.

Irvine's researches were interrupted by the First World War; at the same time, however, the experience of the St. Andrews school was brought into full play in meeting the demands of the British, French and Russians for such indispensable carbohydrates as dulcitol, inulin, fructose, maltose and mannitol. There followed the complete preparation, in quantity, of novocain. These tasks, together with difficult and dangerous work on mustard gas, hindered the expansion of the fundamental researches on carbohydrates. This work was once more getting into stride when Irvine became principal in 1921.

Soon afterwards, the scientific contributions that the new principal had made to the national war effort were recognized by the bestowal upon him of a knighthood; he had been elected a Fellow of the Royal Society in 1918. A portrait of this fourth professor of chemistry in the United College of St. Salvator and St. Leonard, painted some years later (1933) by Oswald Birley, hangs in the Senatus Room of the University of St. Andrews beside that of his teacher, predecessor and friend, Thomas Purdie. A distinguished pupil of Irvine has said that "he was an inspiring teacher, and his lectures were models of clearness. More than that, they inspired in the students a love of chemistry and gave them a desire to take part in the discoveries that Irvine himself was initiating".

Irvine had shown his administrative ability as professor and also as dean of the faculty of science; but few suspected his latent powers until the broad opportunities of the principalship unfolded themselves before him. A profound love for his University and an unfailing faith in its high destiny enabled him to combine the vision of the seer with the drive of the man of action, and to use tradition as the handmaid of progress and development. He cherished the picturesque attributes of his ancient University, and drew into practical service the pageantry and colour of the 'College of the Scarlet Gown'.

During his long term of office, the development of the residential system with its attached Harkness entrance scholarships, together with the institution of regents, played a leading part in widening the field of recruitment of students and in raising their number to an economic level. New chairs were founded judiciously in every faculty of the University. Among many notable advances in the part of the University situated in Dundee were the growth of the schools of medicine and engineering, and the expansion of the chemistry department of University College. These rapid developments, combined with the geographical handicaps imposed upon a University with centres situated upon both sides of the Tay, have inevitably given rise to growing pains. Such difficulties, however great, must be overcome in the interests of the University as a whole. In Irvine's own words (1950): "Let it be an encouragement and an inspiration to each one of us to reflect that, within the history of our own times, obstacles so formidable have been met and surmounted. . . . I have faith, unconquered and unconquerable, in the beloved University of St. Andrews".

Irvine's interests and activities, although concentrated upon the University of St. Andrews, spread outwards in ever-widening circles as the years went by. He took a great and practical interest in preserving the historical character of the city of St. Andrews. In the outside world he rendered invaluable services to the Scottish Universities Entrance Board, the Scottish Education Department, the Forest Products Research Board, the Carnegie Trust, the Pilgrim Trust, the Commonwealth Fund, and many other organizations. He was a member of the Prime Minister's Committee on the Training of Biologists (1931), chairman of the Viceroy's Committee on the Indian Institute of Science (1936), of the Committee on Higher Education in the West Indies (1944), and of the Inter-University Committee on Higher Education in the Colonies (1946–51). He was a prime mover in founding the University College of the West Indies, where the scarlet student-gown of St. Andrews may be seen in a new environment. He was also an ever-welcome visitor to the United States; on various occasions he delivered special lectures and addresses in that country, as at Williamstown (1926), Princeton (1929), and Yale (1931).

He was awarded many honours: in 1948 he became K.B.E.; in chemistry he was Longstaff medallist of the Chemical Society, Davy medallist of the Royal Society, Willard Gibbs medallist of the American Chemical Society, and Elliott Cresson medallist of the Franklin Institute of Pennsylvania. He received numerous honorary degrees from the universities of the homeland, the British Commonwealth and the United States.

He married in 1905 Mabel Violet, younger daughter of Mr. John Williams, of Dunmurry, Co. Antrim. Throughout his subsequent career he owed much to his wife's unfailing devotion and counsel, and to the background of a happy home-life. He had three children, including one son, Nigel, who died on active service during the Second World War.

It is difficult to do justice in words to Irvine's many-sided character and personality. A richly stored mind found expression in speech that could attain a rare eloquence and charm, whether at great moments or upon more intimate occasions. He was an admirable chairman, ever ready to lighten the routine of business with an apt anecdote or reminiscence. He had a remarkable power of reducing a complicated problem to its essentials; at the same time, he had an equally remarkable memory for detail of all kinds. Persuasive in argument, tenacious of opinions carefully formed, he showed the greatest determination and forcefulness in carrying through a cherished project passionately held. He was a stern disciplinarian when occasion demanded; yet his students knew instinctively that in him they had a firm friend. He had, indeed, a discerning sympathy with youth; he would sometimes pause at his desk in the midst of the weightiest matters in order to write a charming letter of encouragement or of congratulation to a youthful acquaintance: from him came many kindnesses of which the world knew nothing. In himself he preserved throughout his life a certain element of spiritual boyishness, allied closely with his eager zest for new knowledge and fresh experiences.

Two years ago Irvine wrote: "I find myself—a twentieth-century scientist—gazing across the chasm of five hundred years to a strange remote world and am conscious afresh of a feeling which never entirely escapes me that, as the thirty-fourth Principal of St. Salvator's College, I am privileged to share in the inheritance of a solemn trust; at once I am brought face to face with the question if the duty committed to that long succession of Masters has been faithfully discharged". The answer is clear to us and will be even clearer to posterity.

JOHN READ

Dr. F. W. Carter, F.R.S.

FREDERICK WILLIAM CARTER, who was until his retirement in 1946 consulting engineer with the British Thomson-Houston Co., died on May 29 at the age of eighty-one.

A man of impressive appearance and of great mathematical ability, he was nevertheless very modest, gentle and reserved. He was almost the first mathematician of high order to apply his abilities exclusively to the practical problems arising during the development of a great engineering industry, and in so doing he built up a world-wide reputation. Behind the mathematics which he used so successfully, he had a clear physical conception of the problems with which he dealt, and in many cases saw the form of the answer before the problem had been worked out in detail. So his analyses included those factors which would give a satisfactory engineering answer, and ignored factors not significant. All his writings are models of lucidity and of the economical use of words, and are a pleasure to read in spite of the difficulty of the subject-matter.

Dr. Carter's choice of subjects was very wide; the first paper published in 1898 dealt with "The Smashing Point of a Glow Lamp"; the last, published in 1944, with "Anti-aircraft Gunnery". Between these two extremes he ranged over many problems both electrical and mechanical. His papers were published in the *Proceedings* of the Royal Society, of the Cambridge Philosophical Society, of the Institution of Civil Engineers, of the Institution of Electrical Engineers, and in many of the important technical journals.

By electrical engineers Dr. Carter will always be remembered for his investigations on magnetic fields in electrical machines. In this work he used the Schwarz–Christoffel transformation, described by J. J. Thomson in "Recent Researches in Electricity and Magnetism". He was the first to apply it to a practical engineering problem, and after a lapse of time, while engineers acquired an understanding of this weapon of attack, others followed his lead. Three papers on this subject were published: one in 1900, another in 1901, and the third, where he collected the results of his researches, in 1926. 'Carter's coefficients', quoted in text-books on electrical design, and used by electrical machine designers, were derived from this work and perpetuate his name.

In mechanical engineering Dr. Carter completed one investigation of outstanding originality. It relates to the running characteristics of locomotives with special reference to their stability of operation. He began, in a paper on "The Electric Locomotive" in 1916, by propounding a theory to explain unstable running of locomotives, introduced and defined a new quantity which he called 'creepage', and made a qualitative analysis for conditions of stability. The subject was developed in two further papers in 1926 and 1928, based on Love's work on elasticity and Routh's work on criteria of stability. A final paper, in 1930, applied these earlier results to analyse the characteristics of certain locomotives involved in derailment accidents. Using models, he gave a practical demonstration of the correctness of his theory at a conversazione of the Institution of Civil Engineers in 1929.

One further sample of his work is worthy of special mention. In 1922 he published a book on "Railway Electric Traction". Thirty years later it is still accepted as the standard book dealing with the fundamentals of the subject.

In addition to his published works, comprising thirty-four papers and one book, he carried out many investigations for the British Thomson-Houston Co., which he served during almost the whole of his professional career. One of these, in 1939, was the determination of stresses in a large forging during heating and cooling and in the transition from the plastic to the elastic state.

He entered St. John's College, Cambridge, in 1892, taking his degree in 1895, when he was placed eighth wrangler. In 1926 he was awarded the Sc.D. degree at Cambridge, the first in the Faculty of Engineering for more than fifteen years, so far as can be traced in the records. He was elected a Fellow of the Royal Society in 1932. He became a full member of the Institution of Civil Engineers in 1919, and was awarded the George Stephenson Medal and the Telford Premium by the Institution. He became a full member of the Institution of Electrical Engineers in 1912, and was awarded a premium for his work on magnetic fields.

He married in 1908 Edith, youngest daughter of James Cramp, of Coventry, and sister of Prof. William Cramp. He is survived by his widow and three sons, the eldest of whom is Prof. G. W. Carter, professor of electrical engineering in the University of Leeds. K. R. HOPKIRK

NEWS and VIEWS

Meteorology in the University of London: Sir David Brunt, F.R.S.

SIR DAVID BRUNT is retiring in September from the chair of meteorology in the University of London and the post of head of the Department of Meteorology in the Imperial College of Science and Technology, London, to which he was appointed in 1934. The Department, the only one devoted to the subject in a British university, has greatly flourished under Sir David's direction and has attracted students from all parts of the world. The research work carried out there has much increased, and the teaching staff, apart from Sir David, has grown to five and includes two University readers. After a brilliant career in mathematics at the Universities of Wales and Cambridge, Sir David became a meteorologist in 1916 as an officer of the Meteorological Section, Royal Engineers. On demobilization in 1919 he was appointed Superintendent of Army Services in the Meteorological Office. This post involved control of meteorological work in chemical warfare and ballistics; thus the study of turbulence and diffusion in the lowest layers of the atmosphere, to which he has since contributed so much, became a major official responsibility. During his service in the Meteorological Office he also made important contributions to the study of periodicity in European weather, to radiation, and to the dynamics of depressions and anticyclones. Shortly after his appointment in 1934 to the Imperial College, he produced his monumental book "Physical and Dynamical Meteorology", in which was given the first full, connected and critical account of those aspects of meteorology. Since then, while not neglecting radiation and turbulence, Sir David has worked mainly on cloud formation by eddy motion, on the effect of atmospheric conditions on human comfort and capacity for work, on the meteorology of soaring flight, and on the application of meteorology to agriculture and industry.

Sir David was elected to the Royal Society in 1939, received a Royal Medal in 1944 for his contributions to meteorology, and became a secretary in 1948 and a vice-president in 1949. He was knighted in 1949. He has also been president of the Royal Meteorological Society, from which he received the Buchan Prize in 1933 and Symons Medal in 1947, and of the Physical Society. He has been a member of the Meteorological Research Committee of the Air Ministry from its formation in 1942. Sir David's work has covered a very wide range and has been characterized by strict adherence to physical reality leading to results of immediate practical value. He has had great influence in stimulating among meteorologists the application of exact physical reasoning to meteorological problems, and among Service officers and engineers in revealing to them the help which meteorology can give in the solution of their problems.

Mr. P. A. Sheppard

MR. P. A. SHEPPARD, University reader in meteorology in the Imperial College, is to succeed Sir David Brunt. He was born in 1907, graduated in 1927 at the University of Bristol with first-class honours in physics and joined the staff of the Meteorological Office in 1929 as resident observer at Kew Observatory. His early work lay largely in the field of atmospheric electricity, and he took part in the British Polar Year expedition of 1932–33 to Fort Rae in Arctic Canada as the specialist in that subject. Shortly after returning from Canada he joined the Meteorological Section of the Chemical Defence Establishment, Porton, and there investigated problems of wind structure in the layers of atmosphere just above the ground. To aid in this work he designed a sensitive cup anemometer of very low inertia and with a linear calibration curve which would record in a wind as light as 40 ft./min. His paper on the aerodynamic drag of the earth's surface published in the *Proceedings of the Royal Society* in 1947 describes a study of the wind drag on a torsionally mounted plate, and establishes the validity of von Kármán's constant in the terrestrial boundary layer. Mr. Sheppard left the Meteorological Office in 1939 to go to the Imperial College; but the outbreak of war brought him back to the Office in the autumn of the same year. His major work during the War was the technical direction of the work of the British *radiosonde* observing stations and of the meteorological reconnaissance aircraft. He also collaborated with Dr. Sverre Petterssen and others at the Central Forecast Office in devising techniques for the use of upper air information in forecasting and in work on the determination of the large-scale vertical currents from the structure of horizontal wind flow. He returned to the Imperial College in 1945 and since then has been actively interested in atmospheric turbulence and cloud structure. He has served the Royal Meteorological Society as a secretary and as editor of its *Quarterly Journal*. Another valuable service to his fellow meteorologists has been the writing of the surveys of progress in meteorology published in *Science Progress*. He is a member of the Air Ministry Meteorological Research Committee, chairman of its Instruments Sub-Committee, and an original member of the Civil Aviation Research Committee.

Zoology at Reading: Prof. C. H. O'Donoghue

PROF. CHARLES H. O'DONOGHUE will retire from the chair of zoology in the University of Reading in September. Prof. O'Donoghue graduated with first-class honours in zoology and physiology in the University of London (King's College) in 1908, and was appointed assistant to the professor of zoology at University College, London. In 1912 he was awarded the degree of D.Sc. and a Beit Memorial Fellowship for Medical Research. He spent six months in Freiburg in 1913 under Prof. Doflein, the protozoologist, and in the following year was elected a Fellow of University College, London. In 1918 he went to Canada as professor of zoology in the University of Manitoba, and was elected a Fellow of the Royal Society of Canada in 1922. He was a member of the Biological Board of Canada. He spent five summers at the Pacific Coast Biological Station at Nanaimo, Vancouver Island, and acted as director during 1923. In 1926 he was visiting professor for two terms at Stanford University, California. He also took part in two biological expeditions to Jasper Park in the Rocky Mountains.

Returning to Great Britain in 1927, Dr. O'Donoghue served under the late Prof. J. H. Ashworth as senior lecturer, later reader, in zoology, in the University of Edinburgh. He was elected a Fellow of the Royal Society of Edinburgh and served on the Council of the Royal Physical Society, becoming its president in 1933. In 1932 he was awarded the Neill Prize and Gold Medal of the Royal Society of Edinburgh for his published researches in the *Transactions* of that Society, and in 1937 was made biological secretary. He became professor of zoology in the University of Reading in September 1939, on the retirement of Prof. F. J. Cole. A new department was being built, and though the outbreak of war caused a cessation of work, building was later resumed and the Department was opened in December 1942. Prof. O'Donoghue was dean of the Faculty of Science during 1944–48, and deputy vice-chancellor of the University during 1950–52. His researches have covered a wide field in zoology. Under Prof. J. P. Hill at University College, he worked on the mammary gland and corpus luteum of marsupials. He has published numerous papers on the vascular system of fishes, amphibians and reptiles; his study of the blood-vascular system of the tuatara, *Sphenodon punctatus*, has become a classic. His later work is taxonomic, and he is an authority on the Nudibranchiate Mollusca and the Bryozoa, having described collections from many parts of the world. Prof. O'Donoghue is a member of the Council of the Zoological Society of London.

Prof. A. Graham

PROF. ALASTAIR GRAHAM has been elected to succeed Prof. O'Donoghue. He graduated with first-class honours in zoology in the University of Edinburgh in 1929, and then took up an appointment as lecturer in zoology in the University of Sheffield, leaving in 1933 to become reader in zoology at Birkbeck College, University of London, under the late Prof. H. G. Jackson. In 1943 he was made head of the Department and professor of zoology in 1947. Prof. Graham is a governor of Birkbeck College. As chairman of the Board of Studies in Zoology, and of the Board of Examiners in Zoology, he has given valuable services to the University of London. Prof. Graham can look back with pride on his achievement in keeping the Department at Birkbeck College going during the War. In 1940 the Zoology Department was destroyed by bombing, though most of the teaching specimens were salvaged. The Department was set up in the condemned building of Graystoke, and when further bombing restricted its activities, classes were carried on in a cellar, and on several occasions in the open air. He preserved the continuity of the Department through every calamity and raised it to its present high status—a department consisting almost exclusively of part-time students, of whom one-fifth are engaged in research for higher degrees. Prof. Graham's research work has been on the functional anatomy of molluscs, with special reference to feeding habits, and the structure and function of the alimentary canal. He has recently been awarded the Keith Prize of the Royal Society of Edinburgh for the period 1949–51.

Sir George Thomson, F.R.S.

A FAREWELL dinner was held on June 24 at the Imperial College in honour of Sir George Thomson, who after twenty-two years as head of the physics department is leaving on August 1 to become Master of Corpus Christi College, Cambridge. The Rector of the Imperial College, Sir Roderic Hill, presided at the dinner, and the Governing Body was represented by its chairman, Viscount Falmouth. Nearly one hundred people attended, representative of present and past members of the staff and the research students; and on their behalf a presentation was made to Sir George of a watchmaker's lathe, this being suitable for the miniature model-making which is Prof. Thomson's favourite hobby. Prof. W. D. Wright, speaking on behalf of the departmental staff, recalled that it was twenty-five years ago, almost to the day, that a letter had appeared in *Nature* entitled "Diffraction of Cathode Rays by a Thin Film"; that letter marked the beginning of Sir George's well-known researches in electron diffraction. Since 1930, at Imperial College, Sir George had directed notable researches in electron diffraction, nuclear physics and cosmic rays, and he had also given valuable service to the Government as a scientific adviser, both during and after the War. Many personal tributes were paid to Sir George by subsequent speakers, who included the Rector, Viscount Falmouth, Prof. H. Dingle and Prof. H. Levy. They emphasized in particular Sir George's penetrating scientific insight, and the deep respect which he had won from all associated with him. Just as his distinguished father, Sir Joseph Thomson, had been affectionately known in his laboratory as "J.J.", so Sir George was always referred to as "G.P.". He takes with him to Cambridge the good wishes of all at the Imperial College of Science and Technology.

Peter Artedi: A Contemporary of Linnæus

THE yearbook for 1950–51 of the Swedish Linné-Sällskapets (Årg. 33–34, 1950–51; pp. iii+188; Uppsala: Almquist and Wiksell, 1951) includes two contributions by Dr. O. Walde and Prof. H. Engel dealing with the biography of Peter Artedi, the friend and fellow student of Linnæus. Artedi was accidentally drowned in 1735 before completing his important work on ichthyology on which his reputation rests. His manuscripts were saved by Linnæus, who edited and published the "Ichthyologia" in 1738, adding a brief biography of the author. Very little is known of Artedi personally, and only one of his letters has survived. Dr. Walde has discovered, in the Royal Library at Stockholm, a small volume dealing with alchemy, botany and agriculture, which was recognized as the work of Artedi. Prof. Engel relates that Artedi lived a lonely life, going to the tavern from 3 to 9 p.m., working from 9 p.m. to 3 a.m., and sleeping from 3 a.m. to noon. This article comments on some of the legal documents connected with Artedi's death and on the personal effects left by him.

A New Anti-malarial Drug: 'Daraprim'

'DARAPRIM', a new anti-malarial drug, has recently been put on the market by Messrs. Burroughs Wellcome and Co. It is 2 : 4-diamino-5-*p*-chlorophenyl-6-ethylpyrimidine, and is the most active of a large series of substituted 2 : 4-diamino-pyrimidines which have been synthesized and tested against laboratory infections of *Plasmodium gallinaceum* in chicks and *P. berghei* in mice (Falco *et al.*, *Brit. J. Pharmacol.*, 6, 185; 1951). Trials in quiescent cases of human malaria have been reported by Archibald (*Brit. Med. J.*, ii, 821; 1951), and in overt infections of *P. falciparum* and *P. malariæ* in man by McGregor and Smith (*Brit. Med. J.*, i, 730; 1952). They concluded that it has a powerful action on schizonts and a lesser and inconstant action on trophozoites. It acted as swiftly in non-immunes as in others possessing partial immunity; it is tasteless and no toxic reactions of any kind were observed. The drug is an effective suppressant of *P. falciparum* infections, even in doses as small as 5 mgm. daily. Goodwin (*Brit. Med. J.*, i, 732; 1952) took this amount daily for one year. During this time he deliberately exposed himself to the bites of four mosquitoes later shown to be infected with *P. falciparum*. He also slept without a mosquito net for six months while in West Africa. Throughout this period there were no toxic manifestations, and no abnormalities were produced in the blood, bone marrow, or urine. To each of a group of volunteers in England, 50 mgm. of the drug was given twice weekly for three months. Again there were no demonstrable effects on the urine, blood, or erythrocyte sedimentation-rate. Although it is too early to assess the value of this drug, and there are as yet no reports on its action in *P. vivax* infections, its schizonticidal efficiency in *P. falciparum* and *P. malariæ* infections appears to lie between that of paludrine and chloroquine, and it may prove to be a highly efficient malarial suppressant.

Geophysical Research Aboard the R.R.S. *Discovery II*

THE R.R.S. *Discovery II* has recently set sail on the second of its current series of research cruises (see *Nature*, May 24, p. 866), and is expected to be at sea for five to six weeks, going about six hundred miles seaward. The main purpose of the cruise is to elucidate the structure of the sea-bed by taking samples of the top strata and by seismic refraction 'shooting' at short and long ranges. The geological sampling will be carried out both in shallow and deep water by means of specially designed coring-tubes, capable of taking cores of the bottom sediment up to 30 ft. in depth. The seismic work will consist of refraction 'shooting' at short range (that is, up to a distance of twenty miles) in shallow water, and at long range (up to a hundred miles) on the edge of the continental slope, on the slope itself, and in oceanic depths; for the short-range work only one ship, equipped with sono-radio buoys, is required, but two ships are necessary for the long-range observations, and H.M.S. *Scott* will assist in this. Other work to be attempted during the cruise will include heat-flow measurements through the bed of the ocean, at a depth of about 2,000 fathoms (12,000 ft.), these observations being made with a specially devised probe which is driven 10 ft. into the bottom sediment and allowed to remain there for a specified time. The purpose of these measurements is to determine whether the heat-flow through a continent originates from radioactivity of the continental-type rocks which are, to a large extent, absent under the oceans. Wave recordings, with the special ship-borne wave recorder fitted for the previous cruise, will be continued as a normal routine, and special attention will be given to echo-sounding, more particularly on the continental slope and in deep water. The ship is operated by the National Institute of Oceanography; during this voyage it will work in co-operation with the Department of Geodesy and Geophysics, University of Cambridge, and the following men of science, among others, will be on board during parts of the cruise: Dr. E. C. Bullard, director of the National Physical Laboratory, Teddington; Prof. W. B. R. King, Department of Geology, and Dr. M. N. Hill and Mr. B. C. Browne, of the Department of Geodesy and Geophysics, Cambridge; and Dr. H. F. P. Herdman, of the National Institute of Oceanography.

Indian Jute Mills Association Research Institute

The formal opening by the Prime Minister of India, Mr. Nehru, on January 2, of the new buildings of the Indian Jute Mills Association Research Institute in Calcutta completes the second part of the Association's post-war scheme of co-operative development, which had already been partly realized by the inauguration of a training college for apprentices (*Nature*, 167, 1058; 1951). The Research Institute, founded in 1936 to provide the type of service usually given by research associations in Britain, was originally housed in central Calcutta, under conditions which left a good deal to be desired by the scientific workers on the staff, and in 1945 it was decided to provide more adequate accommodation in the suburbs. The new premises provide modern amenities for a staff of 85, including 45 qualified scientific men or technologists. Laboratories for physics (4), chemistry (4), biological sciences (3), X-ray crystallography, optics, testing, dyeing, finishing, and chemical technology; administrative offices, a lecture room, library, canteen, stores and workshop occupy most of the 50,000 sq. ft. of floor space in the two-storied air-conditioned building. Among the laboratory services are included laid-on compressed air and vacuum. In order to prepare the staff for making the best use of the new laboratories, senior members of the various sections (physics, chemistry, testing, etc.) have been sent to Great Britain during the past five or six years for training in research; the majority of these went to the University of Leeds and qualified for higher degrees in textile science or technology. The director of research of the Institute is Dr. W. G. Macmillan.

Safety of Domestic Electrical Installations

A paper entitled "Domestic Electrical Installations—Some Safety Aspects" was presented on January 24 to the Utilization Section of the Institution of Electrical Engineers by Mr. H. W. Swann, who is senior electrical inspector of the Factory Department of the Ministry of Labour and National Service. The paper gives a comprehensive review of the hazards commonly arising from electrical faults in domestic consumers' installations, and of the methods of protection employed and their limitations. Statistics relating to fires attributed to electrical causes are quoted for the period 1946–50, and attention is directed to the question of the effect of the age of electrical installations on fire risk. Detailed consideration is given to the effect of leakage current on fire and shock risks. It is emphasized that with the increased load now taken by many domestic consumers, normal fuse-settings are often sufficiently high to prevent operation with the maximum fault current that can flow in the 'earth loop', and in this connexion the advantages and limitations of earth-leakage protection devices are discussed. It is suggested that changes in method may become necessary and that the inspection and test of protective devices may prove to be more practicable than large-scale inspection and test of installations and appliances already in use. The paper constitutes a much-needed reminder that means of protection of consumers' installations which were satisfactory at an earlier stage, when electrical energy was utilized on a much smaller scale than to-day, are being rendered ineffective by the sheer growth of the consumption of electricity.

Training of Designers for the Printing Industry

A report on the training of designers for the printing industry prepared by a subcommittee of the London and Home Counties Regional Advisory Council, Higher Technological Education (Report No. 11; obtainable from the Council, Tavistock House South, London, W.C.1; pp. 20; 1952; 1*s*.), recommends that training courses for this purpose should be held in, or in association with, colleges containing reasonably comprehensive departments of printing. In allocating practical accommodation to classes in colleges, it is recommended that priority should be given to classes for apprentices under the indenture approved by the Joint Industrial Council. Local education authorities are recommended to ensure that their scholarship arrangements permit financial assistance for specially selected apprentices attending part-time classes to transfer to full-time attendance for a course in design, and trade associations should consider offering a limited number of scholarships to enable gifted apprentices to take full-time courses in design. Practical instruction in trade processes—to the limited extent recommended—should, for students in a four-year full-time design course, be confined to the last two years. The report is manifestly concerned solely with technical education—the basic principles by which the training of designers for the printing industry should be guided in the future. Nowhere in the report is there any concern with higher technological education, and on the evidence of this report the title itself of this Regional Advisory Council is one more illustration of the sad confusion between technical and higher technological education which appears to be impeding the formulation of an adequate and effective policy for either.

Society of Cosmetic Chemists of Great Britain: Officers for 1952–53

THE fourth annual general meeting of the Society of Cosmetic Chemists of Great Britain, which is an associate of the Society of Cosmetic Chemists (U.S.A.), was held at the St. Bride Foundation Institute, London, on June 13. Mr. W. A. Poucher was elected as the Society's first honorary member. The following officers and members of council were elected for the year 1952–53: *Chairman*, Dr. R. H. Marriott; *Vice-Chairman*, F. V. Wells; *Honorary Secretary*, F. Hulley (24 Bride Lane, Fleet Street, London, E.C.4); *Honorary Treasurer*, E. Polan; *Members of Council*, A. B. Bell, Dr. H. W. Hibbott, H. Holmes, Dr. A. W. Middleton and J. Pickthall.

University of Glasgow: Appointments

THE following appointments have been made in the University of Glasgow: G. Hoyle (zoology) and R. B. Morrison (bacteriology) to lectureships; F. C. Flack (physics) and M. F. Grundon and H. J. E. Lowenthal (organic chemistry) to Imperial Chemical Industries, Ltd., research fellowships. P. A. Sweet, lecturer in astronomy, has resigned from the University on his appointment as assistant director of the London University Observatory and lecturer in astronomy at University College, London. The following promotions have been made in the University: Dr. G. Pontecorvo (genetics) and Dr. H. S. D. Garven (histology) to readerships; J. R. Atkinson (natural philosophy), J. A. Downes and Dr. J. D. Robertson (zoology), and Dr. J. D. Loudon and Dr. J. C. Speakman (chemistry) to senior lectureships; B. W. Ribbons (botany) and I. C. Smith (zoology) to lectureships.

National Research Council of Canada Scholarships for 1952–53

THE National Research Council of Canada has recently announced the award of its scholarships for the academic year 1952–53. The details are as follows, with the corresponding figures for last year in brackets. Altogether 241 (215) awards have been made, totalling 227,900 (192,100) dollars in value, of which 65 (72) are bursaries, worth 600 dollars each, 114 (92) are studentships worth 900 dollars, and 39 (30) are fellowships at 1,200 dollars each. Eighteen special scholarships at 1,500 dollars have been awarded for study in universities or institutions abroad, to be held as follows: four at Cambridge, three at Oxford, two each at Cornell, London and North Carolina, and one each at Chicago, California, Edinburgh, Illinois and at the John Innes Horticultural Institution, Hertford. Five overseas post-doctorate fellowships at 2,500 dollars have been granted for work at universities, two being at Oxford, and one each at Cambridge, Dublin and London.

Institution of Electrical Engineers: Premium Awards

THE Institution of Electrical Engineers has made the following award of premiums for papers read or accepted for publication during the session 1951–52. *Institution Premium:* D. P. Sayers, Dr. J. S. Forrest and F. J. Lane. *Kelvin Premium:* Dr. A. L. Cullen. *John Hopkinson Premium:* T. H. Flowers. *Non-Section Premiums:* Dr. H. L. Haslegrave (Llewellyn B. Atkinson Premium); J. E. Flood and Dr. J. R. Tillman; and P. R. Howard. *Measurements Section Premiums:* Prof. F. C. Williams, Dr. T. Kilburn, G. E. Thomas and Dr. A. A. Robinson (Silvanus Thompson Premium); D. F. Lawden (Mather Premium); and J. V. L. Parry. *Radio Section Premiums:* Dr. R. N. Bracewell, Dr. K. G. Budden, J. A. Ratcliffe, Dr. T. W. Straker and Dr. K. Weekes (Duddell Premium); T. Kilvington, F. J. M. Laver and H. Stanesby (Ambrose Fleming Premium); Dr. A. T. Starr, T. H. Walker, H. Grayson, T. S. McLeod, R. A. G. Dunkley, G. Dawson, G. King, L. Lewin, J. Lipinski and J. B. Setchfield; D. J. Harris and R. J. Ryan; J. T. Machowicz; N. G. Meadows; P. N. Prior and A. J. Walsh.

Announcements

THE Albert Medal of the Royal Society of Arts has been awarded to Sir Frank Whittle for the development of the continuous-combustion gas turbine and jet propulsion.

SIR ALAN DRURY is to retire on September 30 from the post of director of the Lister Institute of Preventive Medicine. He will be succeeded by Dr. A. A. Miles, deputy director of the National Institute for Medical Research and director of its Department of Biological Standards.

THE following announcements have been made by the University of London: Mr. J. R. Napier, lecturer in anatomy at St. Thomas's Hospital Medical School, has been appointed to the University readership in anatomy tenable at the Royal Free Hospital School of Medicine from October 1. E. C. Cherry, an appointed teacher at the Imperial College of Science and Technology, has been awarded the degree of D.Sc.(Eng.).

THE title and status of reader in zoology in the University of Leeds has been conferred upon Dr. T. Kerr, senior lecturer in the Department of Zoology. Dr. R. Brown, reader in plant physiology in the Department of Botany, has been granted leave of absence by the University for the period October 1, 1952–September 30, 1953, to enable him to accept an invitation to an appointment as visiting professor at Cornell University.

AN 'open-day' will take place at the National Fruit and Cider Institute, Research Station, Long Ashton, Bristol, on July 15, when the annual meeting of members will be held and the laboratories, cider house, etc., inspected.

A SYMPOSIUM on New Research Techniques in Physics will be held at Rio de Janeiro, São José dos Campos and São Paulo, Brazil, during July 15–29, under the joint sponsorship of the Brazilian Academy of Sciences, the National Research Council of Brazil and the Centre of Scientific Cooperation for Latin America (Unesco). Further information can be obtained from Prof. J. Leite Lopes, Centro Brasileiro de Pesquisas Fisicas, Avenida Pasteur 250, Rio de Janeiro.

PROF. J. Z. YOUNG asks that attention be directed to a mistake in the description of the support provided for research on the flying spot microscope described in *Nature* of June 7, p. 963. This work has been made possible by grants from the Nuffield Foundation and from the Research and Development Division of the British Steel Founders' Association which, in connexion with its industrial health research, is particularly concerned with the high-speed counting of dust particles.

IDENTIFICATION OF ORGANIC COMPOUNDS FROM INFRA-RED SPECTRA

By Dr. A. E. MARTIN

Sir Howard Grubb, Parsons and Co., Newcastle upon Tyne

MOST organic chemists are well aware of the assistance to be gained from a study of the infra-red spectra of their compounds; but probably many do not realize just how valuable infra-red data could be if a complete catalogue of spectra were available. At the present time several organizations, mainly in the United States, are collecting spectra from many laboratories; but the total number has scarcely reached 3,000 and is only increasing at the rate of about 1,000 per annum, so that clearly progress will have to be greatly accelerated if anything like a complete catalogue is to become available in an acceptable period of time.

It is the purpose of this article to point out that with a little concerted effort fairly complete data of the spectra of organic compounds could be recorded in a reasonable period, notwithstanding that a recent estimate[1] puts the total number at about 500,000, of which some 70,000 can be regarded as the more common; this is approximately the number listed in the "Dictionary of Organic Compounds" by Heilbron and Bunbury. A simple method of recording and filing spectral data is also described.

Experimental Procedure

A modern double-beam spectrometer with rock-salt prism is capable of recording a spectrum from 2 μ to 15 μ with sufficient resolution for our needs in twenty minutes or less, so that allowing for repeat runs and the fact that for the present purpose it is only proposed to use the spectral region 7–15 μ, it should be possible to record the spectrum of a given substance in one hour, say eight compounds per day, 40 per week and 2,000 per annum. With ten instruments fully occupied in this way, 20,000 spectra could be recorded in a year, 100,000 in five years and 500,000 in twenty-five years.

It is desirable that the work should be carried out with a comparatively small number of instruments, since then greater control could be exercised over the accuracy and uniformity of the results. It would be a simple matter to arrange for each instrument to record the spectrum of a given test substance once a week, so that a high standard of accuracy could be maintained.

The question of how a spectrum shall be obtained from a given substance is one of considerable difficulty, and careful consideration is desirable before deciding on a rigid procedure. Comparatively few compounds exist as liquids or solids of low melting point; these can be examined in the liquid state. Many substances can be examined in solution at low concentration (about 1 per cent) in carbon disulphide or carbon tetrachloride, while intractable materials of high melting point and low solubility can be examined as a suspension in 'Nujol' (medicinal paraffin). The 'Nujol' technique is extremely useful, as practically any organic substance, liquid or solid, can be examined in this way. Inevitably a fair proportion of the incident radiation is scattered and lost, but in general this need not exceed 30 per cent. 'Nujol' has strong absorption at 1,450 and 1,375 cm.$^{-1}$, but this latter band causes little interference below 1,350 cm.$^{-1}$ and no other important absorption is encountered in the region used. In the case of rare substances or very small samples, an adequate spectrum can be obtained with as little as 30 μgm. by using a simple reflecting microscope in conjunction with the spectrometer.

The supply of pure substances from laboratories all over the world would be necessary for the successful operation of the scheme; but this should present no great difficulty since the quantity required is very small.

For the purpose of recording the salient features of a spectrum, the positions of the six most intense bands will in general be sufficient. The concentration of the substance under investigation and the length of cell would be chosen so that the strongest band reaches about 80 per cent absorption. Bands will then be quite sharp and the relative intensity of the stronger ones readily determined. If the weaker of the six bands correspond to less than about 20 per cent absorption, it will be desirable to record further spectra at a higher concentration or with a longer length of cell.

The region of the spectrum to be utilized is limited to 650 to 1,350 cm.$^{-1}$ (the so-called fingerprint region), since the frequency-range 1,350–5,000 cm.$^{-1}$ is unsuitable for our present purpose. The 3-μ region is valuable in elucidating details of structure, particularly with regard to OH, NH, NH$_2$, CH, CH$_2$ and CH$_3$ groups, but to make full use of this region greater resolution is required than is normally obtainable with a rocksalt prism. Between 2,800 and 1,800 cm.$^{-1}$ few important frequencies occur, so that this interval is not of great interest. At about 1,750 cm.$^{-1}$ the important carbonyl frequency occurs; but this is easily recognized and need not be included in the present scheme. Similarly, the CH$_2$ and CH$_3$ deformation frequencies at about 1,450 cm.$^{-1}$ are quite easily picked out, together with the CH$_3$ deformation frequency (symmetrical) at 1,375 cm.$^{-1}$; they can also be excluded.

Filing System

In order to classify bands between 650 and 1,350 cm.$^{-1}$, this region is conveniently divided into seventy 10 cm.$^{-1}$ intervals. In most cases sharp bands are available which can be measured to $\pm$ 2 cm.$^{-1}$. Band positions can be entered on punched cards, and machines are available for sorting the cards in various ways, to find a match for the spectrum of the unknown. However, even with only 100,000 cards, the sorting process would be lengthy and the necessary machines are quite costly, so that it would scarcely be possible for many laboratories to install such equipment. Fortunately, a much simpler and cheaper alternative is available. By dividing the spectra into 70 × 70 groups, each spectrum can be classified according to the positions of the strongest two bands. If the interval 650–659 cm.$^{-1}$ is called number 1, 660–669 cm.$^{-1}$ number 2, and so on to 1,340–1,350 cm.$^{-1}$, which would be designated number 70, a spectrum with its most intense band at 1,071 and its next strongest at 796 cm.$^{-1}$, for example, would be classified as 43/15.

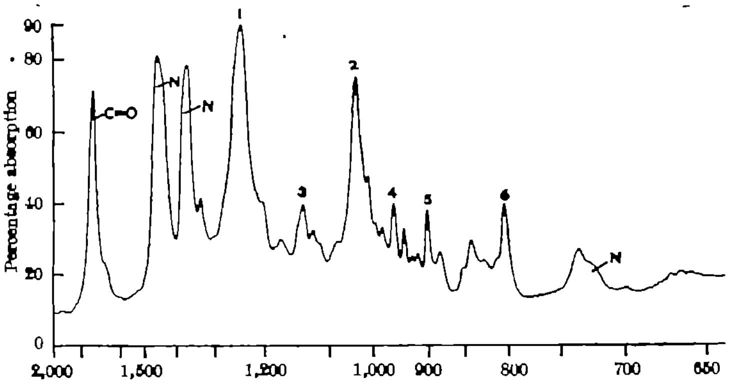

Fig. 1

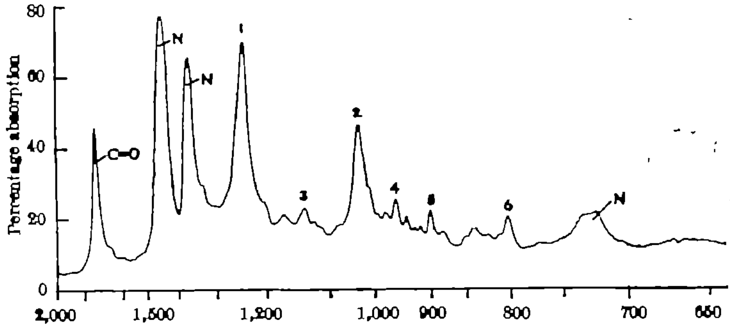

Fig. 2

Absorption spectra of cholesteryl acetate at two different 'concentrations' in 'Nujol'; length of cell, 0 01 mm.; recording time from 1,350 to 650 cm.$^{-1}$ 7 min. *N* denotes absorption due to 'Nujol'

Cards would be filed in order from 1/1, 1/2, etc., to 70/1, 70/2 . . . 70/70, and since there would be 4,900 classification numbers there would be, for a total of 500,000 compounds, something of the order of a hundred substances for each classification number.

With the details of thirty or forty compounds printed on a single card, three cards would, on an average, suffice for each classification number, and some 15,000 cards would be required for 500,000 substances. Quite a modest set of filing cabinets would house this number of cards. Once the strongest two bands have been measured in the spectrum of an unknown, it is the work of seconds to pick out the cards containing details of all compounds with their strongest two bands in the same 10 cm.$^{-1}$ intervals as in the unknown. At the worst, it is then only necessary to look through the spectral details of some hundred compounds to find one which matches the unknown.

It might be thought that the scheme as outlined so far, while possible for relatively simple substances, would fail with larger and more complicated molecules, on account of the large number of conflicting absorption bands. That this difficulty is not so serious in practice is shown by the spectrum of cholesteryl acetate, a fairly large and complex molecule (see Figs. 1 and 2). The two key bands in order of intensity are 1 and 2, while the others in order of diminishing frequency are numbered 3, 4, 5 and 6. The classification number is therefore 60/40 and the entry on the card would read:

No of spectrum	Molecular formula	Absorption frequencies
——	$C_{29}H_{48}O_2$	1,244, 1,040, 1,138, 960, 902, 804

It is not necessary to classify the four weaker bands in order of intensity, except that when the absorption is less than 20 per cent (the strongest band corresponding to 80 per cent absorption) the frequency can conveniently be underlined to direct attention to the fact. By placing the four weaker bands in order of frequency, it becomes a simple matter, when identifying an unknown substance, to select the most distinctive band of the four and to look rapidly through all the compounds with the proper classification number to pick out any with a band in the same position. A detailed check with the remaining bands would, of course, be made to establish the identity of the two substances. If an impurity frequency happened to be chosen as the most distinctive of the four weaker bands, probably only one or two spectra at the most would have a band in the same position, and a check with the remaining bands would cause these compounds to be rejected. It would then be wise to repeat the search using another of the four bands.

In some cases it may even be possible to identify major impurities. After the bands of the main constituent have been eliminated by reference to the spectrum of the pure material, the remaining bands can be dealt with in the usual way, the strongest two being used to obtain the classification number.

Each spectrum of a known substance is given a number for the purpose of identification, and a separate index will, of course, be necessary, so that the full chemical description of the compound and classification number corresponding to a given spectrum number can be found. Conversely, if the spectral details corresponding to a known chemical compound are required, it is only necessary to look up the substance by name, obtain the classification number and then look through the cards with this number to find the desired spectral data. If more detailed information is required, recourse must be had to the original spectrum, which can easily be located once its number is known.

Some Difficulties

R298

Of course, various difficulties could arise in putting the project into operation. For example, the spectrum of an unknown might have among its strongest bands several of similar intensity, so that the selection of the most intense and next strongest for determining the classification number is not straightforward. As an illustration, if a substance has nearly equally intense bands at frequencies denoted by *X*, *Y* and *Z*, it will be necessary to use the combinations *XY*, *YX*, *XZ*, *ZX*, *YZ* and *ZY* to exhaust all possibilities.

Yet another difficulty might be caused by one or both of the key bands of a pure substance being broad or of complex structure, so that the frequencies could not be measured with the usual accuracy. In this case the unsatisfactory bands would be discarded for the purpose of obtaining the classification number.

This should not cause much difficulty in practice, since a similar situation would arise when the same substance occurred in an unknown, and as soon as the unsatisfactory nature of one or more of the stronger bands was realized, less intense but better defined bands would be employed. Unsatisfactory bands not used for obtaining the classification number could be bracketed to distinguish them. As already mentioned, when the intensity of bands is less than 20 per cent, the frequencies would be underlined. If a band is superimposed on a continuous background of absorption, allowance should be made for this when assessing the band intensity. The simplest procedure is to take the height of a peak above any part of the immediate background free from distinct bands. Both the above-mentioned points are illustrated by the following imaginary entry:

No. of spectrum	Molecular formula	Absorption frequencies
—	—	(930), (1,387), 803, 997, 1,284, 705

The classification number would now be 16/35.

If the spectrum of the unknown has its strongest bands at, say, 801 cm.$^{-1}$ and 1,239 cm.$^{-1}$, besides looking up the cards corresponding to 800–809 and 1,230–1,239, that is, 16/59, it would be wise to look up also the classifications 15/60, 16/60 and 15/59, in case small errors have occurred in the measurement of these key frequencies.

Costs

The cost of the project as outlined, apart from the initial cost of equipment and cost of the organic substances themselves, might be expected to amount to possibly £20,000 per annum to keep ten spectrometers working continuously and to cover the cost of printing data cards. This works out at about £1 per spectrum produced for an annual output of 20,000 spectra. The cards of data could be brought up to date and redistributed as necessary each year. Each laboratory possessing an infra-red spectrometer and wishing to make use of the service would take the complete set of data cards issued each year. It is reasonable to suppose that in time at least a hundred laboratories in Great Britain alone would require the cards of data, so that an annual charge of £200 would make the project self-supporting. After only one or two years, the value of the service should be well worth this sum.

COSMETICS AND DERMATITIS

At a recent meeting of the Society of Cosmetic Chemists of Great Britain, held at the St. Bride's Institute, London, a lecture on "Cosmetics and Dermatitis" was given by Dr. E. J. Moynahan, consulting dermatologist to Guy's Hospital.

Referring briefly to the history of cosmetics, Dr. Moynahan mentioned the fact that several different types of cosmetic are described in the Ebers Papyrus, and that many references to such preparations are to be found in the works of the alchemists and early herbalists. The empirical approach has continued to dominate cosmetic art and practice, however, until comparatively recent times. A noteworthy contribution to scientific study has been made by Sulzberger and others, who have begun to segregate and classify the various causes of dermatitis.

Very few primary irritants are used in modern cosmetics. Those that are found include permanent-waving reagents, which attack the keratin chemically and break down disulphide linkages; depilatories of closely related type; high concentrations of alkali; and oxidation hair-dyes such as *para*-phenylenediamine. Most of the relatively few cases of dermatitis provoked by cosmetic materials are due to sensitization.

Dr. Moynahan referred to the considerable protection provided by the skin's horny layer (if intact) and its supernatant layer of sebum against the majority of external agents, with the exception of such keratolytics as strong alkalis and acids. Dermatitis, which occurs in the lower rather than keratinous layers—that is, in the living cells—varies from redness and itching to swelling, vesicle formation and finally to necrosis. Oils and predominantly oily emulsions, owing to their ability to penetrate through the lipoids of the skin, are more likely to favour the onset of dermatitis than are aqueous solutions and mainly aqueous emulsions, although factors other than the constitution of the vehicle have also to be considered. High proportions of wetting agents may lead, for example, to an undesirable concentration of active agents below the prickle cell level.

In discussing typical cases of sensitization, Dr. Moynahan pointed out that primary irritants may in turn become sensitizers. With a few notable exceptions, such as the azo dyes and amine intermediate dyes, sensitizers are unfortunately difficult to classify in chemical groups, owing to the lack of exact knowledge of the response mechanisms of the skin. It is not always easy, therefore, to predict from chemical data the tendency to irritate the skin of newly introduced chemicals. Skilfully conducted patch tests are valuable; but, however carefully chosen be the concentration of product, size of patch and site of application, such tests have their limitations.

In a general review of cosmetics as causes of dermatitis, Dr. Moynahan said that occupational dermatitis, due to the handling of cosmetics, is comparatively rare. This may be partly attributable to the employment of automatic methods for mixing, filling and so forth. Face creams rarely give trouble except when irritant perfume materials have been incorporated in them. The same observations apply to face powders. Permanent-waving reagents give the most trouble, followed by hair dyes. Allergic dermatitis provoked by hair dyes is dramatic in character but in most cases easy to treat. In cases of lipstick dermatitis there is usually a history of exposure to ultra-violet light; indelible dyes such as eosin are photosensitizers (as is also bergamot oil, used in eau-de-Cologne, etc.). All brands of lipstick tend to give the same reaction in such cases of idiosyncrasy. Nail-lacquer dermatitis occurs mostly on the thinly keratinized skin around the eyes and on the chin or cheek; not on the fingers themselves. Several of the constituents of plastics have been known to act as sensitizers. A cause of nail brittleness which is more common than nail varnish solvents is the injudicious use of some of the newer detergents. Most of the anionic detergents used in cosmetics are satisfactory in the proportions normally employed: more trouble has been caused by other detergents and wetting agents used in the washing and treatment of fabrics. Rouge is virtually innocuous in character. As the keratin of hair is tougher than that of the skin, it would appear that depilatories are bound to affect the skin keratin. For the purpose of depilation, Dr. Moynahan said that he prefers the method of electrolysis, although this method is impracticable for axillary hair removal in women. After briefly referring to cases of oil dermatitis caused by the use of 'brilliantines', he interpolated some comments on keratoplastics and then referred to the merits and defects of barrier (protective) creams. His concluding remarks dealt with the indiscriminate use of disinfectants, which can easily intensify skin irritation, and with the potential dermatitis-provoking action of highly rosined soaps.

COPENHAGEN BIOLOGICAL CONFERENCE

RECENT developments and present trends in cellular biology, physiology and chemistry formed the subject of a joint Danish–British conference held during April 30–May 2 at the Danmarks Farmaceutiske Hojskole in Copenhagen. At the invitation of Danish biologists and the University of Copenhagen, a group of research workers from Great Britain as well as several Danish scientific workers reported on the progress of their own researches, dealing with a variety of topics, which were chiefly, though not exclusively, concerned with the correlation of cell composition with specific cell functions such as growth, division and survival.

The opening session, at which the chair was taken by Dr. A. F. Hughes, began with Prof. H. G. Callan's account of his studies on the amphibian oocyte nuclei; he was followed by Dr. W. S. Bullough, who spoke on the effect of œstrogenic hormones on carbohydrate metabolism and mitosis in mouse ear epidermis; and Dr. M. Webb on the influence of certain extraneous agents, chiefly magnesium, on cell division in bacterial cultures. Dr. F. Buchthal presided at the next session, which was devoted to papers by Dr. J. M. Mitchison, on the mechanical properties of the cell surface, particularly in relation to cleavage; Dr. E. Zeuthen on nuclear growth and respiration in dividing marine eggs, in the light of his recent experiments with the refined Cartesian diver technique; and Dr. C. Waymouth on the problems of maintenance and growth of tissues *in vitro*, in a variety of media of chemically defined composition.

The chair at the next day's meeting was taken by Dr. G. H. Bourne and Prof. P. Brandt Rehberg. The proceedings were opened by Drs. E. C. Slater and K. W. Cleland, who discussed the respiratory and phosphorylative ability of heart muscle sarcosomes. Dr. S. R. Pelc and Dr. A. Howard followed with a communication on the effects of X-rays and neutrons on the synthesis of deoxyribonucleic acid in plant roots; Dr. H. Holter surveyed critically the existing methods by means of which different parts of the cell can be separated mechanically and used for studies on the localization of enzymes in the cytoplasm; Dr. R. Brown described the enzymatic changes which occur in the plant cell during growth. A much appreciated contribution was made by Prof. K. Linderstrøm-Lang, who analysed in a detailed manner the phenomena of diffusion and precipitation in Gomori's histochemical test for phosphatase. Dr. E. Hoff-Jørgensen spoke on the deoxyribonucleic acid content of some bacteria in relation to requirements for vitamin B_{12}.

Prof. J. N. Davidson took the chair on the last day of the meeting. Dr. H. Kalckar described recent experiments in which he used radioactive phosphorus for the demonstration of a pyrophosphorolysis of uridinediphosphoglucose to uridinetriphosphate and glucose-1-phosphate; Dr. R. Markham reported on some new structural characteristics of nucleic acids as revealed by the combined application of enzymic and chromatographic methods; Dr. J. A. V. Butler then spoke on the action of radiomimetic substances on nucleic acid; and Dr. C. Lutwak-Mann on the behaviour of nucleic acid in blood-forming tissues with special reference to X-ray injury.

The contributions were followed by stimulating comments and discussion, notably by Prof. C. H. Waddington, Drs. J. Ebling, J. A. Kitching, R. K. Morton and others. In conjunction with the conference three evening lectures were given. Dr. D. J. Bell reviewed the subject of "Transglycosidation: a Natural Method of Stored-energy Transfer" before the Danish Chemical Society; Dr. T. Mann spoke on "Sperm Survival and its Dependence on Metabolic Processes" to the Danish Biological Society; and Prof. J. Z. Young on "Experiments on Learning in the Octopus" to the Natural History Society.

The British party, who enjoyed initially the support of Dr. M. Swann and later of their efficient secretary, Dr. W. S. Bullough, were most cordially received and entertained by their Danish colleagues. Prof. H. V. Brønsted, Dr. H. Holter, Dr. H. Kalckar, Prof. K. Linderstrøm-Lang and Dr. E. Zeuthen spared no effort to assure for the conference the maximum of scientific and social success. A banquet at the ancient Munkekaelderen was honoured by the presence of the rector of the University of Copenhagen, Prof. H. M. Hansen.

INTERNATIONAL UNION OF BIOLOGICAL SCIENCES

MEETING OF THE EXECUTIVE COMMITTEE

THE executive committee of the International Union of Biological Sciences met in London in the rooms of the Royal Society during March 4–5. This meeting was midway between the last General Assembly of the Union at Stockholm in 1950 and the next one to be held in the summer of 1953. Thirty members of the executive committee, from eight countries, were present, representing the nine Sections of the Union, namely, those of Biometry, Botany, Experimental Cytology, Embryology, Entomology, Genetics, Limnology, Microbiology and Zoology. Some of these Sections are identified with international bodies; thus the Section of Biometry is constituted by the Biometrical Society, the Section of Experimental Cytology by the Society of Cell Biology, the Section of Microbiology by the International Association of Microbiologists, and the Sub-Section of Zoological Nomenclature by the International Commission on Zoological Nomenclature. The executive committee expressed the desire that all Sections of the Union, some of which are already affiliated to the permanent committees of International Congresses, should as far as possible be identified with international organizations having similar activities and aims. Another wish was formally expressed that substantial financial aid be sought from international foundations for scientific establishments of the Union, in particular for the two centres of systematics and of experimentation which have been created by the Commission of the Union for Research on the Biological Control of the Pests of Plants.

The Union organizes annually a limited number of discussion symposia. In 1951 three were held on, respectively, cytochemistry, symbiosis in insects, and biometry in relation to plant growth. This year four are to be held: on the bacteriophage, at Royaumont near Paris; on cytodifferentiation and histodifferentiation, in Stockholm; on the scientific organization of botanic gardens, in London; and on the biochemical and structural bases of morphology, in Utrecht.

The International Union of Biological Sciences, which has been in existence since 1919, is a member Union of the International Council of Scientific Unions, and from time to time, as the need for them arises, joint commissions which last a few years are established between it and other Unions of the Council; for example, a new Joint Commission on Electron Microscopy with the International Union of Pure and Applied Physics has just been set up. The International Union of Biological Sciences possesses limited funds furnished by the subscriptions of its thirty-one member countries, and it acts in an advisory capacity to Unesco for expenditure by that body on biological sciences. Further information can be obtained from the general secretary of the Union, Prof. P. Vayssière, 57 Rue Cuvier, Paris.

BRITISH GELATINE AND GLUE RESEARCH ASSOCIATION

FIFTH RESEARCH PANEL MEETING

THE fifth research panel meeting of the British Gelatine and Glue Research Association was held at Beale's Restaurant, Holloway Road, London, N.7, on Tuesday, April 29, at which the total attendance of about seventy included staff of member firms, and of other research associations and government departments. The chair was taken by Mr. S. G. Hudson, chairman of the Association.

The first paper was given by Dr. J. T. Edsall, professor of biological chemistry in Harvard University and Fulbright visiting lecturer in the University of Cambridge. In his paper, entitled "The Conversion of Fibrinogen to Fibrin", Prof. Edsall commenced by underlining the striking character of the gel-forming process in blood clotting, shown all the more clearly when the purified protein constituents, thrombin and fibrinogen, are mixed in solution and a firm rigid gel is formed in a short period of time. The gel-forming ability is so great that Dr. J. D. Ferry has obtained fibrin gels at a concentration of 0·004 per cent. The two main stages in blood clotting are the formation of thrombin from prothrombin and, secondly, the thrombin–fibrinogen interaction which leads to clotting. It has proved possible to obtain purified prothrombin from which thrombin can be prepared for studies of its action on fibrinogen. Thrombin clearly acts catalytically, since the amount required to convert a substantial quantity of fibrinogen into fibrin is very small (1 part per million of fibrin). Quantitative studies of its enzyme action are, however, difficult to perform owing to adsorption of thrombin on the fibrin formed. Fibrinogen represents some 4 per cent of human plasma proteins and up to 10 per cent in beef plasma and the plasma of other animals. It has been separated by salting out or by low-temperature alcohol precipitation.

Flow birefringence, ultracentrifuge studies, diffusion and light-scattering give evidence of a molecular weight for fibrinogen of 400,000–500,000, the molecule being markedly elongated. Approximate dimensions are, for a rod-like shape, length 700 A. and diameter 38 A. Electron microscope studies by C. Hall, while confirming these figures in the main, show a considerable variation in length from molecule to molecule, and the structure appears bead-like along the length of the molecule. The sub-units may be related to observations of the action of urea in breaking down the molecule to give units of molecular weight in the region of 100,000. The molecular weight of thrombin is not known definitely, but is probably less than 100,000.

The early stages of the action of thrombin on fibrinogen have been shown by Lorand, Bailey and co-workers to involve the release of end-groups which can be estimated by Sanger's fluoro dinitrobenzene technique, giving a frequency of roughly one group per 100,000 molecular weight. In addition, 3–4 per cent of the protein weight is split off as a peptide, the composition of which is being studied. At *p*H 5 there is no evidence of clot formation when fibrinogen and thrombin are mixed. It is clear that some action occurs even in these conditions, since on raising the *p*H instantaneous clotting occurs, whereas in a mixture freshly made at the higher *p*H there is a time delay before clotting. Light-scattering indicates the formation of intermediate aggregates 2500–4000 A. long prior to setting. These aggregates are formed by the modified fibrinogen after loss of the peptide.

By appropriate choice of conditions (*p*H, salt content) the type of clot obtained can vary from a clear transparent stable gel to a doughy opaque mass easily giving rise to syneresis. The difference depends on the size of the fibrillar units, as has been confirmed by electron microscopy. The coarse clots are the basis of the fibrin films developed by J. D. Ferry and P. R. Morrison for use in neuro-surgery. The effects of *p*H, salt concentration, urea, guanidine hydrochloride, etc., on rate of clot formation have all been studied.

Electron microscope studies of the fibrils in the coarse type of clot show a periodic structure with a spacing of 230 A. reminiscent of the collagen structure. There is no ready explanation of this periodicity. The type of bonding appears to vary according to whether calcium, and a plasma component, are present or not. In the absence of these two, urea suffices to cause dispersal of the clot, but with both present it appears likely that more permanent links involving —SH groups are formed.

The second paper was given by Mr. E. Bradbury, of the British Cotton Industry Research Association, Shirley Institute, Manchester, and bore the title "The Effect of the Temperature of Preparation on the Mechanical Properties and Structure of Gelatine Films". Mr. Bradbury explained the significance of this work as fundamental to the study of the use of gelatine for rayon sizing. Gelatine films prepared by drying at 20° C., 70 per cent relative humidity, and at 60° C., 70 per cent relative humidity, differ appreciably in their properties. Tensile tests on the films after subsequent conditioning at different relative humidities showed that those prepared at 20° C. were stronger than those prepared at 60° C. At low humidities they were also rather more extensible before rupture occurred, but at high relative humidities the 60° C. films became very extensible. At 85 per cent relative humidity their extension at rupture was 129 per cent compared with 23·8 per cent for the 20° C. films. Further experiments showed rate of drying, and the moisture content left in the film at the conclusion of drying, to be of minor importance compared with the temperature of drying. With the guidance of X-ray diffraction results, a theory has been put forward attributing the differences to differing degrees of crystallinity in the films.

The discussion on Mr. Bradbury's paper was opened by Dr. Conmar Robinson, who made use of results on optical rotation and diffusion to put forward an alternative explanation based on two configurations of the gelatin chain. The high-temperature form is presumed folded, with internal hydrogen bonding, whereas in the low-temperature form intermolecular hydrogen bonds occur. Mr. A. G. Ward described results of dilute-solution viscosity measurements on gelatin solutions at 25° C. and 10° C. There appears to be no change in shape in the isolated molecules with temperature, although a slow aggregation occurs.

The final paper was given by Mr. R. A. G. Knight, of the Forest Products Research Laboratory, Princes Risborough, with the subject "Glue Testing at Risborough". Mr. Knight outlined the development of testing procedure and made clear the basic principle of choosing test conditions related to those which the glued joints or plywood are required to withstand in practice. The importance of both plywood and glued joints for the aircraft industry during the Second World War placed great emphasis on behaviour under full exposure to the weather, since aircraft were often parked for months on end in the open. The way in which the Forest Products Research Laboratory drew on the experience of the glue-manufacturing and wood-working and -using industries was described.

MAKERERE COLLEGE: THE UNIVERSITY COLLEGE OF EAST AFRICA

IN 1922, the Uganda Government opened a technical college at Makerere, one of the royal hills of the Kabakas of Buganda just outside Kampala. In 1924 a Government medical school and teachers' training course were also started at Makerere. Gradually all trades courses at the technical college were passed over to a neighbouring institution, and agricultural and veterinary courses took their place; a school certificate course was also developed. By 1937 the College had developed a corporate life of its own and, in that year, the De la Warr Commission recommended that Makerere should develop into a centre of higher education for East Africa; this had long been the wish of the founders of Makerere. From this time the College was to cease to be a Government institution and was to possess an independent Council composed of representatives from all the East African Territories whose Governments jointly made themselves responsible for its finances*.

As secondary schools developed in other parts of East Africa, the academic standards at Makerere quickly rose and, in 1945, the Asquith Commission on Higher Education in the Colonies confirmed that the College should press forward towards university college status. In 1949 it was announced that the College had entered into special relationship with the University of London, and the way was therefore opened for degree courses at Makerere.

The path was now clear for a programme of rapid expansion. On the recommendation of the Inter-University Council for Higher Education in the Colonies, early in 1950 the British Government promised the College £1,100,000 from the Colonial Development and Welfare Fund towards a programme of building development, and the East African Governments quickly responded by guaranteeing annual grants for a five-years development scheme totalling annually approximately four times their previous contributions. The programme already embarked on aims at raising numbers in steps from the present 240 students to 630 students and some 85 members of staff by 1955. The new medical school buildings, opened by the Secretary of State for the Colonies in May 1951, are already in use. The first of the new men's halls of residence, providing accommodation for 180 students, is now complete and was occupied at the opening of the new session in March 1952. An arts faculty building and a new physics laboratory building is also about to be brought into use. A start has been made on the first new women's hall of residence, further staff houses and a science workshop. Other buildings now at the drawing or planning stage include a new chemistry laboratory building, an agriculture block, a second men's hall of residence, a library which it is hoped will provide for the eventual needs of a university of some 2,000 students, and the adaptation of a number of existing buildings to provide further accommodation for biology and satisfactory premises for an enlarged school of art.

Makerere was started for Africans, and by force of numbers it will inevitably and rightly always remain predominantly an African college. The College's Charter, however, laid it down that it was to be open to all the peoples of East Africa. In 1951 the College Council determined that with the opening of new accommodation a start should be made in this direction. It was decided that, for the coming year's entry, six places should be reserved for qualified non-Africans; in fact, an English candidate has already been offered a place for the coming year, and there are a number of Indian candidates. The one stipulation made in admitting members of all races as well as of all religious persuasions is that all should share the common residential life.

The qualification demanded for consideration for admission is the possession of the Cambridge School Certificate (Overseas) with three credits. In practice there are already many more qualified candidates for admission than can be taken. As schools develop in number and quality the matriculation standard will be raised.

The admission problem for girls is far harder than that for boys. Though Uganda and Zanzibar have full girls' secondary schools, neither the first girls' school in Kenya nor the first in Tanganyika has yet reached a School-Certificate form, though both are due to do so within the next two years. Meanwhile, only a few girls have qualified for matriculation through predominantly boys' schools. Most of the women accepted for Makerere under "Special Entry" conditions have had some years teaching experience in primary schools, and, though they often find it a hard struggle to survive academically, some of them develop during their life at the College a hitherto hidden maturity. The whole question of the College's contribution to women's education is at present being studied with the help of an advisory committee of persons engaged in this sphere in the territories.

---

* *Universities Review*, **24**, No. 2.

Like the sister Colonial university colleges, Makerere is in special relationship with the University of London so far as its courses for the B.A. and B.Sc. degrees are concerned. The College takes the initiative in putting forward its own proposals for syllabuses which it submits to the relevant Boards of Study of the University. The process of negotiation up to the final stages is carried through informally between opposite numbers. Similarly, the College examiners submit the first drafts of the Intermediate and Final degree papers and do the first marking of the scripts, which are then sent by air mail to the University of London examiners for the final determination of results. It is too soon to assess the full potentialities of the scheme.

If Makerere is to serve East Africa's needs as a university it will also have to become a centre of research. A start has been made. There are two research schemes for which the College has taken responsibility but which are separately financed from Colonial Development funds—the East African Institute of Social Research under the directorship of Dr. Audrey Richards, and a scheme to investigate malnutrition and anæmia under Prof. Eric Holmes, the head of the College's physiology department.

The most critical problem at Makerere is the recruitment of staff. Not only will Makerere have to find men and women with the necessary specialized qualifications to teach at university-level, but among them those who are willing to offer their experience and skill and adapt them to the teaching problems and the opportunities of an African university college.

STATISTICS FOR COLONIAL AGRICULTURE

IN January 1947 the Agricultural Economics Research Institute of the University of Oxford was asked to undertake a review of the organization and methodology of agricultural statistics in Colonial territories, in the light of reports received from the various Colonial Administrations.

The report, prepared by Mr. K. E. Hunt of the Institute*, opens with a useful selection of statistical series for first study, followed by a programme, in broad outline, for obtaining such data, first of all on a small (village) scale, with later developments either more intensive or more extensive. The first section concludes with a suggested set of definitions of terms used in agricultural statistics. Succeeding sections deal in more detail with techniques appropriate to the various kinds of information sought. A glance at the 'contents' gives some idea of the comprehensive nature of the review. There are sections on village studies (3), extensive surveys (4), crop yield and production estimation (7), crop production forecasting (8), mixed crops (9), tree crops (10), land utilization (11), livestock populations and output (12), and two sections on marketing and distribution. With the more intractable problems of the later sections, the detail is naturally less. Under these headings many other important practical topics, such as recording technique, approach to selected communities, sample selection, correction of bias in eye estimation, crop cutting techniques, etc., are discussed.

Various methods and the results of much valuable experience both in office and field—in preparation, planning, inauguration, execution, analysis and reporting—are thus brought together. By clearly defining the main features in each of these situations, whether difficulties, possible approaches or points to consider, and including actual examples, the report makes most informative and stimulating reading. Many suggestions will need but slight modification to suit the locality. Matters, more of experience than principle, such as preparation of schedules and questionnaires, measuring areas, tabulation, analysis and records are dealt with in the appendixes.

The extremes of excessive detail but limited application and of discussions in abstract general terms are alike avoided; instead, principles are described in homely terms, statistical refinements not being considered necessary at the present. This publication will surely do much to satisfy a long-felt need.

G. E. HODNETT

ABORIGINAL RAIN-MAKERS

IN many parts of Australia droughts have an appalling effect upon the sources of food of an aboriginal tribe, and it is not surprising to know that both the black and the white man have sought to stimulate Nature to greater generosity with her life-giving rains. The ways in which they seek to induce rain are described by Frederick D. McCarthy in the *Australian Museum Magazine* (10, No. 8).

The aborigines desire rain at specific times both for individual and for group or collective purposes. A man attempts to create a storm or shower to obliterate footsteps when eloping with a woman, or, if he is a criminal, escaping the vengeance of his victim's friends. The making of rain, however, becomes a serious matter when it is organized by a local group whose reason may be the overwhelming one of survival in a drought-stricken land, or the desire to carry out important seasonal ceremonies upon which the life-giving power of the community depends; a local group may wish to punish another one by sending storms to spoil their hunting and fishing.

The rites are usually performed during the day; but the Yaroinga of Queensland have one method in which special songs are sung during the night. The rain-maker uses his deep knowledge of local weather conditions as a guide and performs his rites in seasons and at times when rain can reasonably be expected; as a result his efforts are often rewarded with success. In many tribes the rites may be performed by any individual; but as a rule there are one or more rain-makers in a local group who either confine their magical activities to this sphere or are fully initiated medicine-men. In most tribes women cannot witness the rites; in others they participate in some methods or perform a simple type of magical act themselves.

---

* Statistics for Colonial Agriculture—Report on the Organization of Recording and Estimating. Colonial Research Publications No. 11. H.M.S.O.) 7s. 6d. net.

The methods employed by the rain-makers are surprisingly varied, originating as they do in a dream, as a traditional rite performed by the dream-people, or from an incident in daily life which has been followed by rain. Many of the methods are imitative of clouds and falling rain, and of aquatic animals; others seek to persuade the ancestral beings to release the rain, and some medicine-men believe they can go up to the sky to open the clouds.

The Dieri and other tribes of the Lake Eyre district believe that the mura-mura, their spiritual ancestors who made and inhabited the earth in the dream-time prior to man's occupation, now live in the sky, and some of them have to be influenced by ceremonies to release the rain from the clouds.

In south-east Australia storms of wind and rain, and also floods, were believed to be sent by enemies to disturb hunting and fishing activities. The Kurnai of Gippsland squirted water from the mouth in the direction from which rain usually came, and sang magical rain chants acquired in dreams by both men and women.

In Arnhem Land pounded bark (used for poisoning fish) is wrapped in grass, weighted in stones, and taken out into either salt or fresh water by a man until his shoulders are covered; here he drops the bundle, sings a song about falling rain, and pushes the water with his hands to represent the rain splashing on its surface. He expects the clouds to form in about three days and the rain to come on the fourth day after this rite. Here, too, a large bundle of green grass fashioned into a human image is buried and when it swells up rain is expected to fall. The rain is stopped by taking the grass out of the water or ground and spreading it out to dry.

AIR MASS CLIMATOLOGY OF THE BRITISH ISLES

SOME simple facts about the air mass climatology of the British Isles, such as the difference between the relative coldness of east and the relative warmth of south-west winds in winter, have been common knowledge for ages. In the second and third decades of this century the Norwegian school of meteorologists, led by V. and J. Bjerknes, elaborated the ideas of Shaw, Lempfert and others to depict the atmosphere as 'organized' not only into cyclonic and anticyclonic systems but also into warm and cold air masses (often referred to respectively as tropical and polar air) with different life-histories. The interplay of different air masses was shown to produce the day-to-day weather changes of the temperate and polar regions.

In a recent Air Ministry/Meteorological Office* memoir, which is a contribution to synoptic climatology, Dr. J. E. Belasco has investigated the more important physical properties of the atmosphere over the British Isles in twenty-one subdivisions of tropical and polar air, using surface and upper-air data for the period 1931–45. The generalized tracks over which the air masses reach the British Isles are shown by maps, and the frequency of occurrence of the air masses and the average temperature and humidity of the atmosphere in them at the surface at Kew Observatory and in the upper air up to 450 mb. (about 6 km.) over the British Isles are set out in tables and thermodynamic diagrams. There is also a discussion of the changes of temperature and humidity which maritime tropical and direct polar air masses undergo as, on their way to the British Isles, they pass over a surface respectively colder and warmer than their lowest layers. With the aid of this memoir, it has now become possible for the first time to explain some aspects of the climate of the British Isles in terms of the incidence and of the physical properties of different air masses instead of describing them statistically by the usual presentation of means and extremes.

The discussion shows that the correspondence between air mass and wind direction is quite rough and far from unique. Thus, north-west winds usually bring a cold air mass with a large fall of temperature with height and associated showery weather; but when an anticyclone remains stationary westward of Ireland, such winds can bring air originating over the sub-tropical Atlantic which has been cooled from below on its way. Again, polar air of a particularly unstable type can come with a south wind having travelled around a stationary depression centred south-west of Ireland. Quite the coldest air mass is, as is well known, the one which comes in winter from Russia and reaches the British Isles from the east or south-east. This air mass has in January a mean maximum temperature of 31° F. at Kew. The warmest air mass in January comes from the Madeira area and has a mean maximum of 53° F. at Kew. In July the temperature differences between the coldest and warmest air masses are nearly as great as in January. Air of west Mediterranean origin has at Kew in July a mean maximum of 82° F. and air direct from the sea north of Norway a mean maximum of 64°. The differences of temperature between air masses in the upper air are larger than at the surface because the primary heating and cooling occur at the surface.

Dr. Belasco's memoir will be of value not only to those seeking a physical explanation of British climate, but also to the weather forecaster in stating the weather to be expected in an air mass the arrival of which he has foretold.

PAPER PULP RESEARCH AT THE DEHRA DUN RESEARCH INSTITUTE

INVESTIGATIONS on the pulping of *illuk* grass (*Imperata arundinacea*) by the soda and the mono-sulphite processes* have been undertaken at the Forest Research Institute, Dehra Dun, at the request of the Ceylon Government, which forwarded samples for the purpose, with the view of ascertaining the respective economics and suitability of the two processes to the species. Research has shown that the cost of chemicals required for pulping the grass by the mono-sulphite process is 38 per cent more than that required by the soda process. Of the two methods of digestion, namely, 'overhead' and 'fractional', as applicable to the soda process, the 'fractional' method of digestion appears to be more suitable, as well as more economical, for pulping of *illuk* grass.

In Indian Forest Leaflet No. 124 of the Research Institute*, R. V. Bhat and N. S. Jaspal discuss investigations on pulps for writing and printing papers from the castor oil plant (*Ricinus communis*). In India, so far, bamboo and *sabai* grass (*Eulaliopsis binata*) are the chief raw materials used in the paper industry. The local supplies of these materials are insufficient to meet the requirements of the existing mills. Bamboos are used in India for a large variety of other purposes, and the *sabai* grass only grows in particular areas. The production of paper in Indian mills in 1949 amounted to 170,000 tons. To meet domestic demands for paper, a large quantity is annually imported, and these demands are increasing. The instalment of further new pulp plants depends upon larger amounts of raw material being available.

Reimold had advocated the cultivation of the castor oil plant in America, as a high-grade cellulose could be produced at a low price owing to the cheapness of the raw material. The castor oil plant is commonly grown as an annual crop in several parts of India for its seeds, from which the oil is obtained, and it is upon the stalks, for the purpose of making pulp, that experiments were made at Dehra Dun. The plant is also grown as a perennial small tree, and this, too, was the subject of research work.

The conclusions arrived at are as follows. Easy-bleaching pulps with satisfactory strength properties can be prepared from stems of castor oil plants by the soda and the sulphite processes, the latter being the more suitable. The stems of the annual and the perennial varieties can be used for pulping without the removal of the bark. The pulps from the wood are short-fibred, whereas those from the bark are long-fibred. Owing to this, pilot-plant experiments will have to be carried out to determine whether these pulps can be used as such for the production of writing and printing papers or whether they must be mixed with long-fibred pulps such as those from bamboos and *sabai* grass. Since in India the castor oil plant is grown for its seeds and oil production, it is considered that the stalks should be available at a cheap rate.

ORNITHOLOGY IN THE U.S.S.R.

THE ornithology of the U.S.S.R. has been somewhat imperfectly known in other countries, especially of recent years. On behalf of the British Ornithologists' Union, Dr. Hans Johansen, formerly professor in the University of Tomsk and now of the Zoological Museum, Copenhagen, has prepared a paper which attempts to review the place of ornithological studies in the U.S.S.R. to-day (*Ibis*, 94, No. 1). Johansen's task has not been easy because no journal devoted entirely to ornithology has been published in the U.S.S.R.; some of the publications containing ornithological articles are unobtainable. Information about articles on ornithology can frequently only be obtained through lists of Russian literature, so that the articles cannot be seen or judged on merit. Although Johansen's survey must, therefore, necessarily be regarded as incomplete, the author is to be commended for undertaking a task which has involved consideration of not less than five hundred publications.

A summary of Johansen's article indicates that the old traditions of Russian ornithology were best and most strongly represented by faunistic reviews which have almost completely surveyed the whole of the enormous country. Large amounts of material were collected in the form of bird-skins, which made possible the systematic revision of many groups of birds. This again made possible broad concepts of the avifauna of the U.S.S.R. as a whole and the numerous zoogeographical and historical faunistic descriptions.

In addition to these old branches of work, new problems have arisen in recent times, as in the rest of the world. Of these, biological and ecological subjects are prominent and, among other things, have led to the production of ecological–geographical monographs on the birds of Russia.

Many investigations have also been made into the problems of bird migration; in addition to ringing and field observations, laboratory experiments have been made, with good results.

Some work has been done on anatomy and physiology in which attempts were made to connect them with biology, ecology and systematics. Investigations on parasites as well as the disadvantages and benefits of birds to forestry and agriculture were specially supported by the authorities.

If the accomplishments of the Russian ornithologists are considered from a wider and more international point of view it can be said that, on the whole, development has proceeded on the same lines as in other countries, though studies naturally show the peculiar influence of the country.

Because of the great extent of the country, from the Baltic to the Pacific Ocean and from high polar latitude to the subtropical conditions in the Transcaucasus, Russian ornithologists have done little work outside their own country. There is, however, the work of Zarudny in Persia and the numerous Russian expeditions made long ago in Mongolia and central Asia. In recent times these works were continued by Sushkin, Tugarinov, Sudilovskaia (Kashgaria) and, more especially, by Madame Kozlova.

The extent and variation of the U.S.S.R. have also been the reason why the so-called line of faunistic research has received special attention. In recent times, according to Russian information, the emphasis has shifted to ecological–geographical characteristics of entire taxonomic groups of birds. This can be regarded as a new branch of Russian ornithology, though publications have not been received in other countries.

Another speciality of Russian ornithology, which was started by Nikolai Severtzov so long ago as 1877, is the profound zoogeographical analysis, which was chiefly combined with historical conclusions. Of the latest achievements, Stegmann's work on the ornithogeographical division of the Palæarctic Region can claim originality, since he provides new methods and techniques of zoogeographical description.

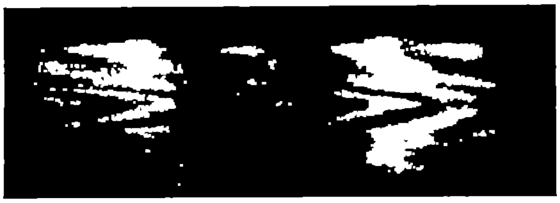
Interference Microspectroscopy

ONE of the main advantages of interference microscopy over phase-contrast microscopy as normally practised is that certain forms can be used for the quantitative determination of the phase change or optical path difference introduced by the object[1]. Not all types of interference microscope, however, are equally suitable for quantitative work, as the phase difference between the interfering beams cannot always be varied continuously. It is therefore useful to have an alternative method of measuring the phase change.

It is well known that, if light from an interferometer system is viewed through a spectroscope, a series of dark bands can be seen crossing the spectrum when a source of continuous radiation is used. When the phase difference between the interfering beams is uniform throughout the field of view these dark bands are straight; but when additional path differences are introduced, as by a refractile object, the bands become displaced and distorted in a manner related to the phase change produced by the object. Thus, if the image of a transparent object such as a cell is projected through an interference microscope on to the entrance slit of a spectrograph, the displacement of the dark bands gives a convenient method of determining the phase change produced at each point of the object the image of which is formed along the slit.

The technique used is similar to that described elsewhere for ultra-violet absorption microspectroscopy[2]. The measurement of the phase change in the object can be applied to the determination of mass as recently described[3]. An unexpected advantage of the method is that the contrast of the bands seen in the spectrograph is much greater than that of the interference fringes in the field of view. Indeed, this type of method is often used for demonstrating the presence of interference effects which may be suspected but cannot be otherwise detected. This is particularly the case when white light is used and when the path difference between the interfering beams is great. The accompanying photograph illustrates this point. The object was an unstained human oral epithelial cell, mounted in water between a semi-rhodiumized slide and coverslip, as suggested by Merton[4]. A tungsten filament lamp was used as source and the separation between slide and coverslip was rather large. The full illuminating aperture of the condenser was used. In these circumstances, no interference fringes whatsoever could be seen in the field of view and the object, being transparent, was virtually invisible. Fringes were quite easily seen in the spectrograph, however, and their contrast could be enhanced photographically without loss of detail.



Interference microspectrograph of epithelial cell, in visible region, taken under conditions of zero contrast in field of view of microscope

We thus have the possibility of obtaining precise optical information concerning an object which cannot be seen under the microscope. Moreover, since the full illuminating aperture is used, the resolving power of the microscope itself is high. The contrast, which may be very low or even zero in the microscope, can be largely recovered in the spectrograph. If the apparatus is adjusted to give good fringes and high contrast in the microscope field of view, the contrast in the spectrograph is very much better than that shown. It is not essential to use a tungsten filament lamp, as most high-pressure mercury lamps emit sufficient continuous radiation between the spectral lines to enable the dark bands to be seen. Such lamps are generally preferable for visual work.

If the object contains absorbing material, anomalous dispersion may occur in the region of absorption bands, so that the refractile and absorbing properties may be simultaneously observed. Finally, at those points which introduce zero phase change, the refractive index will be equal to that of the mounting medium at the same wave-length.

I wish to acknowledge the help received as Johnston, Lawrence and Moseley Research Fellow of the Royal Society.

Thermal Measurements on Small Transient Systems

EXPERIMENTS recently carried out in this laboratory have shown that it is practicable to heat the wires of a thermocouple by the passage of an electric current and at the same time to record the temperature of the junction by means of the thermo-E.M.F. A high-frequency current is used in order that the concomitant voltage (order 10 volts) may be separated from the thermo-E.M.F. (order 0·001 volts) by means of inductance-capacitance filters. The apparatus can be used for measuring the thermal constants of poor conductors placed in contact with the couple wires.

It has been found convenient to pass a pulse of current (after which the system returns to its original state) and to make deductions from the E.M.F.-time record obtained during the heating period. If the pulse is long enough for a steady state to be achieved, the highest temperature is inversely proportional to the thermal conductivity; otherwise both conductivity and specific heat have to be considered. Calculations made by Dr. S. Paterson and Miss Jean

Substance with which wire was in contact	Proportion of energy retained by wire after 96 msec.	
	Observed	Calculated
Medicinal paraffin	0·57	0·52
Castor oil	0·48	0·48
Glycerol	0·33	0·38
Water	0·19	0·28

Davidson have shown that it is in principle possible to calculate absolute values of these quantities from a single record. In practice it has not been yet possible to do this, because available couples are not perfect cylinders; comparison with theory has shown that they behave in this work as though they are 50–100 per cent larger than the nominal diameter of the wire. Nevertheless, measurements made relatively either to the original state of a given system or to a system having well-established properties have been possible. The precision of these measurements is indicated by the accompanying table, in which calculated and observed values of the energy retained by the wire after being heated at a steady rate for a chosen time are compared. In obtaining these figures the values for castor oil have been made to agree by an arbitrary adjustment equivalent to the assumption that the wire is 1·64 times its nominal diameter. The time chosen is such that both thermal conductivity and specific heat play an important part in determining the results.

The method has advantages over conventional methods, notably in speed and in the minimum size of the system on which measurements are practicable: with, for example, 40 S.W.G. wires, which are not inconveniently fine, a measurement takes only 100 msec. and the system need be only 1·0 cm. long by 0·1 cm. in diameter. Moreover, because the average temperature need not be controlled for long periods, measurements at elevated temperatures offer no particular difficulties. The method is therefore very suitable for studying small transient systems such as exist in the reaction zones of thermal self-propagating reactions; it is at present being used for measuring how much the thermal conductivity changes when reaction is propagated in mixtures of iron and potassium permanganate[1].

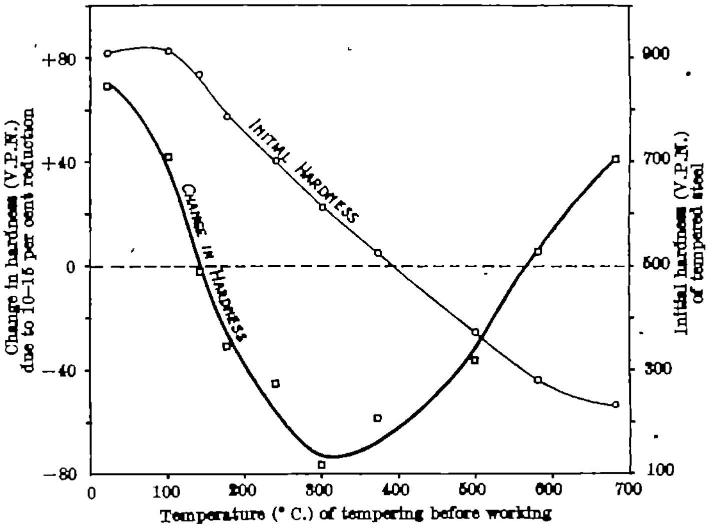
Magnetic Properties, Internal Strains and the Bauschinger Effect in Metals

Polakowski[1] has recently drawn some general conclusions about the behaviour of metals during reversed deformation, and has suggested that the influence of reversed straining on certain properties, including intensity of magnetization, may be predicted on this basis. Since not all changes which may result from plastic deformation are associated with reversible internal strains, however, the behaviour of a change of unknown cause cannot be predicted. On the other hand, if it be concluded on the basis of experiment[2] that the change in the Curie temperature of cementite in cold-worked steels is directly related to the textural stresses set up between the cementite and ferrite, then it may be expected that this effect will give a more certain indication of magnitude of strain in the cementite particles of a steel than can be derived from hardness tests.



Influence of previous heat-treatment on the change in indentation hardness due to 10–15 per cent reduction in height by compression. 0·88 per cent carbon steel, water-quenched from 800° C., immediately cooled in liquid oxygen, and then tempered at the temperatures indicated for 2 hr., before deformation. Hardness values represent the mean of 12 readings taken within 2 hr. of straining. (Increase in hardness of specimens tempered below 140° C. may be under-estimated due to local cracking)

In this connexion I suggest that, in order to understand the mechanism of the work-softening effects discussed by Polakowski, it will be necessary to consider the nature of the textural stress systems present in the different materials. In the case of the softening observed in hardened and tempered steels after moderate degrees of cold-working, for example, a textural stress system which is effectively isotropic on a macroscopic scale is partially replaced by a directional system and, in general, the reduction in indentation hardness is not accompanied by any softening in the direction of working.

The extent of 'work-softening' effects may depend not only on the intensity and directional characteristics of the initial textural stress patterns but also on their scale.

The accompanying diagram summarizes results showing that, in the case of a heat-treated 0·88 per cent carbon steel, the change in indentation hardness which results from a moderate degree of deformation is dependent on the microstructure (approximately the reductions were those which cause the maximum degree of 'work-softening'). Up to a certain limit, about 600 Vickers Pyramid numeral in this case, with increasing initial hardness the magnitude of the softening effect increases progressively. At higher hardness values, however, the observed softening is less, although the initial internal strain energy will continue to increase with hardness. Martensite tempered below about 140° C. does not show the softening effect. Probably rather similar patterns of behaviour are shown by certain age-hardening alloys.

A possible explanation of these effects may be visualized in terms of the suggested influence of the scale of the internal stress pattern on the movement of dislocations in solid solutions and duplex alloys[3]. When the separation of particles of the precipitate is sufficient to allow the formation of dislocation loops around individual particles, then the initial internal stress pattern may be greatly modified as a result of plastic deformation, and indentation tests may indicate abnormally low rates of work-hardening during the early stages of deformation.

However, it is possible that the behaviour of steel, which shows marked strain age-hardening effects, may be complicated by the influence of carbon atoms associated with the ferrite.

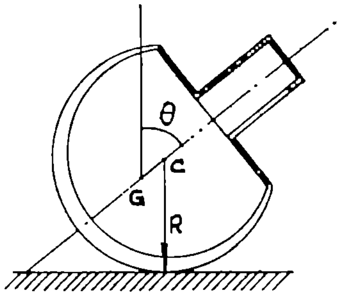
The Symmetrical Spherical Top

A TOP with a cross-section as shown in the accompanying diagram exhibits, when spinning on a horizontal plane, a surprising effect: the stem, which originally points upward, moves away from the vertical while continuing to rotate about this direction, until it touches the supporting plane; whereupon the top quickly rises on the stem and continues its rotation in this stable position. A similar behaviour is shown by a sphere consisting of two halves of different specific weight. If the initial angular velocity is large enough, the centre of gravity will rise until it reaches the highest position possible, the sphere then rotating about its axis of symmetry.



It is possible to show[1] that this effect is due to the friction arising when the point of contact slides over the supporting plane. The torque resulting from this force causes the angular momentum vector to move over the surface of a cone with vertical axis. Thus the angular momentum will have a component perpendicular to the plane through the vertical and the axis of symmetry, which effects a change of the angle θ between these two lines. In this way the following two effects can be described:

(1) If the centre of gravity, G, lies eccentrically in a sphere with axially symmetric distribution of mass, while the moments of inertia about the axis of symmetry and another axis through G perpendicular to the former are equal, the rotation will be stable if the position of G is as high as possible.

(2) If G coincides with the centre, C, of the sphere, while the moment of inertia, A, about the axis of symmetry differs from that, B, about an axis through G perpendicular to the former, stable rotation will be about the axis with the greatest moment of inertia.

The two effects can combine with different results, all of which are characterized by the vanishing of the sliding motion of the point of contact.

(3) If G is eccentric and $A \neq B$, the stable equilibrium value of θ is:

$$\theta = 0 \text{ or } \theta = \pi \qquad \text{if } \frac{A-B}{A} > \frac{GC}{R},$$

$$\theta = \pi \qquad \text{if } -\frac{GC}{R} < \frac{A-B}{A} < \frac{GC}{R},$$

$$\cos\theta = \frac{GC}{R} \cdot \frac{A}{B-A} \quad \text{if } \frac{A-B}{A} < -\frac{GC}{R}.$$

The value of θ given for the latter case is an approximation which is valid at high rotational energy.

A homogeneous sphere with a cavity near a point of the surface is an example of the first case of (3), the sphere with the two halves mentioned above of the second one. An example of the third case of (3) is a sphere, which except for a concentration of mass near a point of the surface, is of homogeneous density. The top shown in the diagram—commercially available in Holland under the names "tippetop" and "toupie magique"—is of the same type. However, before the equilibrium value of θ is reached the stem will touch the supporting plane. The effect due to the eccentricity of G is strengthened then and the top rises on the stem.

Tanning of Fatty Acid and Protein Monolayers by Metal Ions (Cr, Al, Fe and Cu)

IT has been shown by Wolstenholme and Schulman[1,2] that metal ions such as Fe, Al, Co, Cu interact with fatty acid monolayers over the pH stability range of the basic metal ions. There were indications that the association could be influenced also by the size and shape of both the fatty acid molecule and the basic metal ionic unit. The present communication shows how these ideas can be applied to the chromium ionic system, together with a direct analogy between the interaction of the basic chromium ion, with fatty acid monolayers, and the tanning of a protein monolayer. Here, the reactivity of the carboxyl group is important in both systems.

It can be readily shown that a chromic acetate solution does not react with long-chain amine monolayers, since there are no basic chromium ions avail-

able over the pH range in which the amine is associated. Strong interaction takes place with the carboxyl group in fatty acids over the pH range in which the di-basic chromium ion exists. This reaction is shown by the change in the area of the solidification of the molecules and the mechanical properties of the fatty acid monolayers on the metal salt solution. These results are summarized in Fig. 1.

Fig. 1,*A* shows how the basic chromium ionic unit can expand to accommodate the increasing size of the fatty acid molecule (that is, from 40 A.^{2} to 80 A.^{2}). This property of the interlinking basic ionic aggregates appears to be greatest with copper, and decreases in the following order[2]:

$$Cu^{++} > Cr^{+++} > Al^{+++} > Fe^{+++} > Co^{++},$$

as shown in Fig. 1,*B* (for myristic acid monolayers).

These results on solidification of fatty acid monolayers by the basic metal ion can be applied to the tanning of protein monolayers. Fig. 2 shows how the rigidity and expansion of the protein monolayer is affected by the basic metal ions, over the same optimum pH range as in the tanning of the fatty acid monolayers. It appears that there is a potential barrier[3] to be overcome by the adsorbing basic metal ion aggregate, due to the positively charged amine group in the protein monolayer. This barrier can be readily overcome by the addition of sulphate ions. This tanning process works well with iron, aluminium and chromium salts, but curiously, not at all with copper. A tannic acid or vegetable tanning[4] of the protein monolayer is given as a comparison. In this case, the amine groups in the protein monolayer are interlinked by the phenolic groups on the tannic acid molecule.

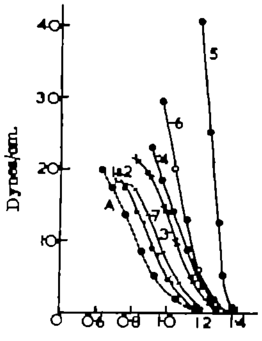

Fig. 3. Bovine albumin films: (*A*) pH 3·8, M/100 sodium sulphate, 18° C.; (1) pH 2·1, M/2,000 chrome alum, 18° C. (1 hr.); (2) pH 3·7, M/2,000 chrome alum, 20° C. (1 hr.), (3) pH 4·21, M/2,000 chrome alum, 17·5° C. (1 hr.); (4) pH 4·76, M/2,000 chrome alum, 18·5° C. (1 hr.); (5) pH 5·26, M/2,000 chrome alum, 18·5° C. (1 hr.); (6) pH 5·71, M/2,000 chrome alum, 18·5° C. (1 hr.); (7) pH 6·07, M/2,000 chrome alum, 18·5° C. (1 hr.)

Fig. 3 shows the complete tanning of bovine albumin monolayers with chrome alum solutions over a pH range which gives a direct analogy with the tanning of fatty acid monolayers.

As was found by Wolstenholme and Schulman[1], minerals containing chromium can be floated by soluble fatty acids over the pH range where the fatty acid monolayers are made insoluble by the basic chromium ions, giving an identical optimum pH range. This shows that chromium ions are available on the mineral surface and form a monolayer network of fatty acid – basic chromium ionic complex, which is hydrophobic.

A Possible Source of Artefacts in the Chromatography of Tissue Extracts containing Inorganic Iodide

Unknown substances containing iodine, apparently associated with inorganic iodide, have been detected in the plasma of patients who had previously received therapeutic doses of radioiodide[1,2]. These substances were discovered by chromatographic separation of the radioactivity present in butanol extracts. The methods of preparation involved paper chromatography with acid solvents[1] and extraction of acidified plasma[2].

Acidification of solutions of inorganic iodide is known to cause the liberation of elementary iodine, and we decided to test the possibility that iodination of unsaturated compounds present in the starting material might take place during extraction and chromatography in acid solutions. Preliminary work on pure substances was clearly desirable; and this communication describes experiments with cholesterol, cholesteryl oleate and triolein, using the radioactive isotope, iodine-131.

0·5 c.c. of a solution of sodium iodide-131 containing 3·5 μC./c.c. was added to 2 c.c. of an acidified aqueous suspension of the lipoid. The suspensions were extracted three times with 5 c.c. of water-saturated *n*-butanol, the layers being separated by centrifugation, and the butanol extracts were evaporated to dryness under reduced pressure on a boiling water-bath. The residues were each taken up in 0·5 c.c. of *n*-butanol. 1-μl. aliquots of the resulting solutions were placed on filter paper strips 2 cm. wide (Whatman No. 1) and chromatographed by the descending method in *n*-butanol/dioxane/2N ammonia, prepared according to Gross *et al.*[3]. The butanol extract of an acidified solution of sodium iodide-131 alone was prepared and chromatographed directly with, and without, the addition of lipoid in ether solution to the spots. For these latter experiments *n*-butanol/dioxane/2N ammonia and *n*-butanol/

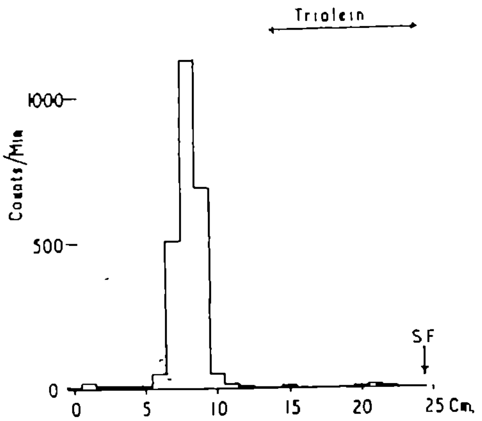

Fig. 1. Distribution of radioiodine on a filter paper strip after chromatography of sodium iodide-131 and added triolein in *n*-butanol/dioxane/2*N* ammonia (*S.F.*, solvent front)

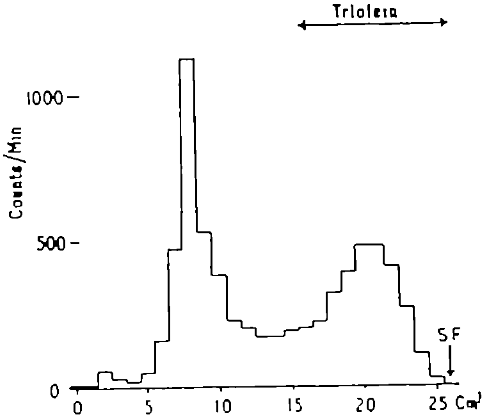

Fig. 2. Distribution of radioiodine on a filter paper strip after chromatography of the butanol extract prepared from an acidified aqueous suspension of triolein to which sodium iodide-131 had been added (*S.F.*, solvent front)

2*N* formic acid (Gross *et al.*[3]) were used as developing solvents in different runs. The lipoids were detected by their fluorescence in ultra-violet light. They formed bands or streaks extending behind the solvent front for distances depending on the amount added to the paper. The radioactivity of each 1-cm. length of the strips was measured separately by means of a Geiger counter fitted with a lead diaphragm. Five-minute counts were made in each position.

Solutions of radioiodide alone, with or without previous butanol extraction, showed one peak of radioactivity ($R_F = 0 \cdot 33$) after chromatography in butanol/dioxane/ammonia. In butanol/formic acid, the R_F of radioiodide was found to be 0·25, but there was some 'tailing' of the spot. In the latter solvent, there was also a small subsidiary peak, the R_F of which was 0·9, representing about 0·5 per cent of the total radioactivity on the paper.

In the case of solutions containing both lipoid and radioiodide, only one large peak of radioactivity was present if iodination did not occur (see Fig. 1). Iodination caused a second peak to appear in the same position on the paper as the fatty substance (see Fig. 2). Fig. 2 demonstrates iodination during extraction from an acidified suspension. Iodination during chromatography with butanol/formic acid gave rise to a similar picture.

No iodination of any of the three lipoids took place during chromatography in alkaline conditions. Cholesterol itself was not detectably iodinated during chromatography in acid conditions and was found to have taken up only 3 per cent of the added radioiodine in the course of extraction from an acidified suspension. Cholesteryl oleate showed significant iodination both during chromatography in the acidic solvent (63 per cent uptake) and during extraction from an acidified suspension (28 per cent uptake). The iodination of triolein resulting from butanol extraction in acid conditions is demonstrated in Fig. 2. During chromatography in butanol/formic acid, this compound took up 32 per cent of the radioiodine present.

It appears likely that artefacts could arise during the preparation and chromatography of tissue extracts containing inorganic radioiodide as a result of reactions similar to those described above. Lipoids may not be the only type of compound involved. Artefacts of this nature could probably be eliminated by avoiding extraction and chromatography in acid solution.

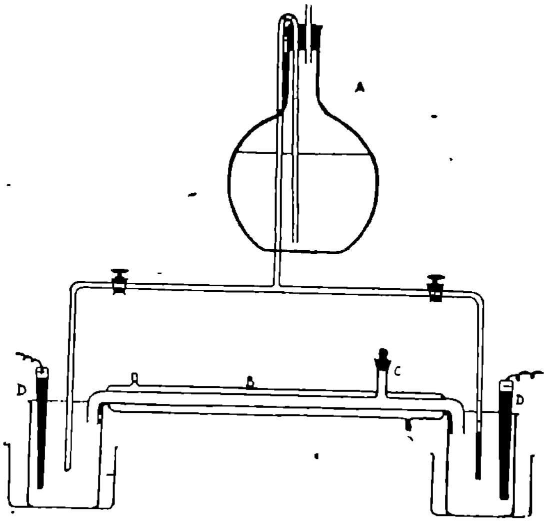
Ionophoretic Separation of Porphyrin Pigments

In the classical Tiselius procedure for electrophoresis of proteins, convection was prevented by the density gradient of the substances under investigation; but complete separation could not thereby be obtained, and the analysis was conducted by the observation of fronts. Later the medium was stabilized by silica or agar gel for the separation of amino-acids[1] and proteins[2]. Silica or agar gel will hold an excess of electrolyte and prevent convection currents; but it will allow substances to pass through independently and to separate into discrete bands. In addition, its use obviates contact of the moving substances with the electrodes.

Since porphyrin pigments are ampholytes, with differing numbers of carboxylic groups, it seemed likely that ionophoresis in a gel would provide a simple means of separation. Nicholas and Rimington[3] observed that the R_F values of porphyrins in paper partition chromatography were inversely proportional to the numbers of carboxylic groups in the molecule.

Agar gel was preferred to silica, since the former is easier to prepare, not so mechanically brittle, and gels in much higher dilution, thereby avoiding the introduction of large amounts of impurities. Nevertheless, stringent purification of the gel preparation was essential to avoid traces of metallic impurities, which would readily form complexes with porphyrins. Treatment with methanol[4] was found unsatisfactory as the product would not gel in the desired concentration. Satisfactory purification was achieved by washing powdered New Zealand agar (Davis) repeatedly with Sorensen *M*/15 phosphate



buffer pH 8·0 and then allowing it to stand over-night in the buffer. The volume was adjusted to give 0·5 or 1 per cent agar and the mixture warmed in the water-bath until solution was complete (half an hour), when it was transferred immediately to the bridge of the ionophoresis apparatus. The agar gelled on cooling, and the residual impurities were removed by ionophoresis for three hours. This treatment appears to replace calcium and magnesium ions of the gel by the innocuous sodium and potassium ions of the buffer[5].

In the subsequent analysis of porphyrin pigments, these were detected by their intense ultra-violet fluorescence. The apparatus could therefore be simplified (see diagram) as compared with that required for proteins.

The procedure was as follows. A small section of agar gel was removed from the bridge *B* via the side-arm *C*, using suction through a Pasteur pipette. The porphyrin solution in *M*/15 phosphate buffer pH 8·0 or in phosphate agar (0·5 ml.) was introduced through *C*, and a direct electric current then passed through the bridge, which was water-cooled as illustrated. With a bridge length of 50 cm., D.C. mains voltage of 200 V. across the carbon electrodes *D* (that is, 4 V./cm.), cooling was not obligatory, but voltages greater than 4 V./cm. caused the temperature to rise higher than 55°, with liquefaction of gel and losses of pigments. Adequate cooling was also advantageous in preserving a steady electric current through the gel. The buffer in the electrode compartments was replaced continuously from the reservoir *A* at the rate of one litre an hour.

After ionophoresis for a period dependent on the voltage applied, the agar was withdrawn by gentle suction into a long glass tube, and the fluorescent portions cut out using a glass microscope slide. Ether-soluble porphyrins were reclaimed by heating the gel with one volume of 20 per cent w/v acetic acid for 30 sec., cooling and extracting immediately into ether. Uroporphyrin was removed by similar hydrolysis of the gel with one volume 5 per cent w/v hydrochloric acid, with subsequent cooling and shaking with chloroform. Traces of unhydrolysed agar were thereby precipitated, and other interfering blue fluorescent material was extracted into chloroform, leaving the uroporphyrin in the aqueous phase.

Our findings were as follows: (1) The porphyrins in untreated urines of acute or congenital porphyria migrated as discrete bands, and the presence of individual pigments was readily apparent. (2) Protoporphyrin (2 COOH), coproporphyrin (4 COOH) and uroporphyrin (8 COOH) had mobilities which increased with higher number of carboxylic groups. (3) Coproporphyrin isomers I and III were not separable, even with a tube 80 cm. long and proportionally greater voltage. Similarly, uroporphyrin isomers could not be distinguished. (4) No separation was observed in a mixture of the dicarboxylic proto-, deutero- and meso-porphyrins. (5) Sensitivity and recoveries were good. 1 μgm. of each porphyrin could be measured, with yields of 60–80 per cent of that amount.

Ionophoresis of porphyrins in agar gel is thus a simple procedure for separation of porphyrin on the basis of constituent carboxylic groups[3]. The effect of other substituents on mobilities at pH 8·0 appeared to be minimal and isomers could not be separated, although separation of coproporphyrin methyl esters has recently been effected by paper partition chromatography[6].

We should like to thank Dr. J. F. Wilkinson, director of this Department, for his continued interest in this work.

The Soret Effect

Although thermal diffusion in condensed systems has been used experimentally for bringing about difficult separations, for example, in the Clusius and Dickel apparatus, and although considerable advances have been made recently in the descriptive treatment of the effect by Prof. S. R. de Groot[1] at Utrecht and Prof. Prigogine[2] at Brussels, experimental data by which theories of the Soret effect may be checked are still meagre.

According to de Groot, the shape of the thermal separation versus time curve is determined by the value of the diffusion constant at the mean temperature. The extent of thermal separation is not predictable, but the theory may be checked by evaluating the diffusion constant from time curves and making comparison with values found by conventional means for known systems.

Some measurements have been made in an apparatus similar to that used by me during 1924–27[3] in which the solution is confined in a shallow layer between horizontal metal surfaces at T and $T + \Delta T$ and optically analysed, without disturbance, by measuring the deviation produced in a horizontal beam of monochromatic light by the changing gradient of the refractive index. The method permits a nearly complete optical traverse to be taken between the top and bottom layers of the cell.

In orthogonally planned experiments with potassium chloride and barium chloride solutions in cells 0·695, 0·975 and 1·396 cm. high, with $T = 25°$ C. and $T + \Delta T = 35°$ C., diffusion constants required to satisfy the de Groot equations were substantially independent of cell height and concentration of solution, and in agreement with literature values for solutions ranging in mole fraction from 0·074 to 0·018 for potassium chloride, and from 0 019 to 0·002 for barium chloride.

The Soret coefficients for the above solutions are small, about 0·1–0·2 per cent per degree, and the measurements provided a test of the sensitivity of the experimental method.

It is hoped to publish the work in detail and to extend it to other systems.

Cellular Permeability of Yeast to Metallic Ions

The apparatus devised by Dr. G. Protti for the kinetic study of cellular metabolism with radioactive isotopes[1] lends itself to permeability studies of yeast. We are using it to study their permeability to different metals.

The metal content of yeast is assumed constant, and the whole of the radioactive isotope is introduced at the beginning of the experiment. Then the rate of disappearance of radioactive metal ions is described by the differential equation:

$$\frac{V}{L}\frac{dx}{dt} = - v \frac{x}{Lb/V} v \frac{(x_0 - x)\, V/L}{a},$$

where a is gm. metal per gm. yeast; Lb/V is gm. metal ion per ml. solution; L is gm. yeast; V is ml. solution; x and x_0 are gm. radioactive metal ion per ml. solution at end and beginning of experiment respectively; t is time in hours; v is permeability measured in $\frac{\text{gm. metal}}{\text{gm. yeast hr.}}$.

Integrating this equation gives:

$$\frac{x}{x_0} = \frac{a.\exp\left(- v\frac{a+b}{ab}t\right)}{a+b} \, .\, b\,;$$

and then:

$$v = - \frac{1}{t}\frac{a.b}{a+b} \ln\left[\frac{x}{x_0} - \frac{b}{a}\left(1 - \frac{x}{x_0}\right)\right].$$

The validity of this equation has been confirmed by experiments using *Saccharomyces cerevisiae* and copper-64 obtained from the Atomic Energy Research Establishment, Harwell; in these experiments, $v = 7·2 \times 10^{-4}$.

Experiments with other metals are still in progress.

A Novel Synthesis for Aroylacrylic Acids

This preliminary investigation was undertaken in an effort to apply the Doebner condensation to the synthesis of aroylacrylic acids according to the following equation:

$$\text{ArCOCHO} + \text{CH}_2(\text{COOH})_2 \xrightarrow{\text{pyridine}} \text{ArCOCH=CH—COOH} + \text{CO}_2 + \text{H}_2\text{O}.$$

The compound chosen for study was 2-naphthylglyoxal, because the properties of the resulting *beta*-2-naphthoylacrylic acid would help clear up certain doubts about its structure at the time this work was begun (however, see ref. 1).

2-Naphthylglyoxal was obtained easily in 75 per cent yield by oxidation with selenium dioxide of methyl 2-naphthyl ketone[2,3]. 2-Naphthylglyoxal monohydrate (15 gm.), malonic acid (7·5 gm.) and pyridine (15 ml.) were stirred for 22 hr. at room temperature. Carbon dioxide was evolved and a solid mass remained. The material was taken up in 5 per cent sodium carbonate solution and acidified to give a gummy semi-solid which hardened on standing several hours. Several recrystallizations from dilute alcohol (decolorizing carbon) gave a 12 per cent yield of bright yellow crystals of *beta*-(2-naphthoyl)-acrylic acid, melting point 164–166° [1] (calc. for $C_{14}H_{10}O_3$: C, 74·32; H. 4·46; neut. equiv., 226·2; found: C, 74·42, H, 4·56; neut. equiv., 227·1). The compound gave a rapid Baeyer's test and positive tests with phenylhydrazine and 2,4-dinitrophenylhydrazine. Tollen's reagent and Schiff's reagents were negative. It was quantitatively hydrogenated at 3 atmospheres pressure over a palladium-on-carbon catalyst to the known *beta*-2-naphthoylpropionic acid, melting point 170–172°. The acid is probably *trans*, since refluxing it with a crystal of iodine in either benzene or chloroform effected no change in the melting point.

Work to be reported elsewhere will show that this novel condensation is adaptable to the synthesis of negatively substituted aroylacrylic acids, such as *beta*-(4-nitrobenzoyl)acrylic acid—which are not obtainable through the conventional Friedel and Crafts reaction—and with considerable increase in yield over that reported here.

Action of Alkaline Hypochlorite on 3 : 5 : 6-Trimethyl-*d*-gluconamide

The action of alkaline hypochlorite upon fully methylated hexonic and pentonic acid amides, using the Weerman procedure[1], results in the formation of cyclic urethanes[2]. Haworth, Peat and Whetstone[3], using this reagent, claimed the direct conversion of 3 : 5 : 6-trimethyl-*d*-gluconamide (which possesses a free α-hydroxyl group) to a 2 : 4 : 5-trimethyl arabinose, isolated as a syrup, to which a straight-chain aldehydic structure was ascribed.

The problem has been re-examined in this laboratory. Purified 3 . 5 : 6-trimethyl-*d*-gluconamide (obtained *via* 1 : 2-mono-*iso*-propylidene-3 : 5 · 6-trimethyl glucofuranose) melted at 138 5° and had $[\alpha]_{D}$ + 38·65° (water). Treatment of this amide according to the Weerman procedure, followed by the method of purification outlined by Haworth *et al.*, gave a syrup with properties almost identical with those described by these workers. However, the application of paper partition chromatography, using as mobile phase one part petroleum ether (100°–120°) and nine parts butan-3-one saturated with water, revealed the presence of at least four components of carbohydrate nature. Methods involving partition chromatography on cellulose columns resulted in the separation of four fractions, three of which each contain a different methylated pentose derivative. The fourth fraction contains little pentose but large amounts of organically bound nitrogen; it has not been further investigated at present.

Fraction 1 was obtained as a mobile syrup having $[\alpha]_{D}$ – 4° (1 per cent in methanol), n_{D} 1·4702 and OMe 34·5 per cent (theoretical value for a dimethyl pentose 34·8 per cent; for a trimethyl pentose 48·0 per cent). An aqueous solution of the syrup strongly reduced Fehling's solution in the cold, decolorized permanganate solution and immediately restored the colour of Schiff's reagent. These properties suggest a straight-chain aldehydic methylated pentose, and we presume this material to be responsible for the similar properties exhibited by the final product of Haworth *et al.*, since no other fractions obtained in the present experiments were capable of producing similar aldehydic effects.

Fraction 2 was obtained in small yield as an immobile syrup having $[\alpha]_{D}$ – 23·7° (1 per cent in methanol) and n_{D} 1·4730. This fraction also apparently consisted mainly of a dimethyl pentose derivative, since its OMe content was 34·4 per cent; but it showed none of the aldehydic properties of fraction 1 and the two fractions behaved very differently when subjected to paper partition chromatography.

Fraction 3, the largest fraction, was an immobile syrup consisting mainly of a trimethyl pentose having $[\alpha]_{D}$ + 13·2° (1 per cent in methanol), n_{D} 1·4718, and OMe 47·9 per cent (theoretical value 48·0 per cent). An aqueous solution of the syrup did not restore the colour of Schiff's reagent immediately, nor did it reduce Fehling's solution in the cold. After treatment with methanolic hydrochloric acid in a sealed tube at 100°, the methoxyl content increased to 59·3 per cent (theoretical value for a pentose with four methoxyl groups, 60 1 per cent) and the optical rotation became lævo, $[\alpha]_{D}$ – 12·5° (1 per cent in methanol), while n_{D} fell to 1·4530. The increase in methoxyl content and the change in the direction of the optical rotation indicate the presence of a hydroxyl group at C 1, and hence some ring structure, most probably propylene-oxidic, for the molecule as a whole.

Progress in this investigation awaits the isolation of crystalline derivatives, since the absolute homogeneity of each fraction is not claimed; and indeed certain chromatographic evidence indicates that fraction 3 may contain more than one trimethyl pentose. It is obvious, however, that under the conditions normally employed in the Weerman degradation reaction, the changes which 3 : 5 : 6-trimethyl-*d*-gluconamide undergoes are considerable and complex and appear to involve loss of methoxyl.

Vision with a Stabilized Retinal Image

The small movements of the eye which persist when a subject fixates (that is, tries to gaze steadily at a given target) have been studied by several workers[1]. We have endeavoured to deduce the movements of the image across the retina from a recent study of the rotations of the eyeball[2]. The movements of the retinal image have the effect of moving the boundary between two regions of differing brightness across the retinal pattern of receptors and may therefore play an important part in vision.

It should be possible, by the following method, to obtain an image which does not move across the retina. The subject wears a contact lens which is specially made to fit his eye tightly and on which a small optical flat has been worked. The flat is covered (by vacuum evaporation) with a highly reflecting opaque film of rhodium. An image I of the object O is focused on to the screen S by means of the optical system shown in Fig. 1. The mirror M is the flat on the lens which is attached to the subject's own eye. The observer views I by reflexion in M_1 and M_2. His visual axis is in the direction V (see Fig. 2). If the distances are suitably adjusted, a small rotation of the contact lens moves I in such a way that the image of I on the retina is stationary. With the simple optical system shown it is possible to obtain compensation for *either* horizontal *or* vertical movements. A more complicated system enables both movements to be compensated at the same time. The adjustment of the optical system may be checked if the eye is replaced by a telescope with a small plane mirror attached to its object glass. When the

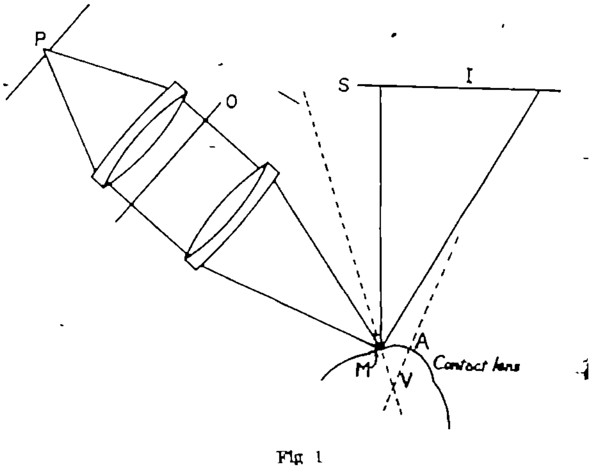

Fig 1

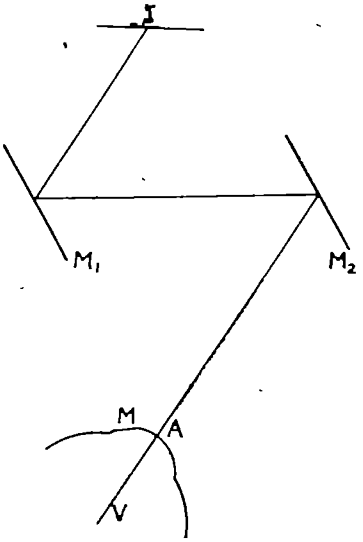

Fig. 2

adjustment is correct, the position of I with respect to the cross-wires is unaffected by a small rotation of the telescope.

Some preliminary experiments were made in 1945 by one of us (R. W. D.) in Dublin. It was found that the stabilized image disappeared at intervals. The results were not then published because they could not be repeated on every occasion, and because the necessary checks could not be made with the equipment then available. It was decided to use the contact lens method for studying the movements in detail before making another attempt to produce a stabilized image.

Recently, a fresh set of experiments has been carried out by the second author (B. L. G.). Only the horizontal components of the movements were stabilized. The object is shown in Fig. 3. The brightness of the right-hand area could be made 30, 40 or 60 per cent of that of the left-hand area. It was found that the line of demarcation disappeared and that A and B appeared to be of equal brightness for two or three seconds at intervals of about one minute. A second observer viewing I in the normal way did not observe any change. Similar effects were observed with other types of target. Although the effect is transitory, it is repeatable. The contrast threshold for the stabilized image is thus very much higher than the normal threshold for the same brightness. It seems that the eye recognizes that the situation is abnormal and makes some adjustment (possibly of accommodation) which temporarily defeats the stabilization causing the image to reappear.

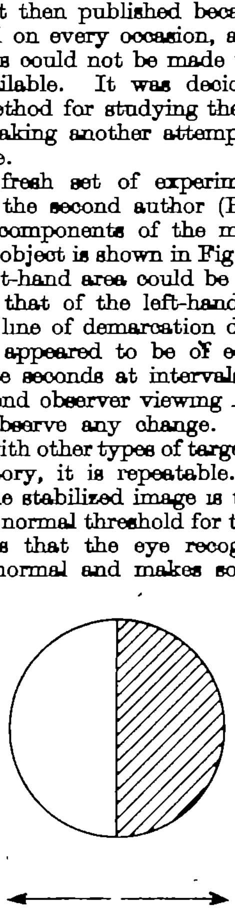

Fig. 3

The present experiments are regarded as showing, in a qualitative way, that the eye movements have a significant function. A further development of technique will be needed to obtain quantitative measurements.

One of us (B. L. G.) was in receipt of a maintenance grant from the Department of Scientific and Industrial Research during the period of this research.

Some Speed, Error and Difficulty Relationships within a Problem-solving Situation

DURING the past three years, experiments have been conducted with subjects who have been given the task of solving mental-test items of a particular type[1] (Thurstone 'letter-series' items). Suppose P_C be the probability that a particular subject will continue to work at a particular problem for some time t before giving it up, and let P_E be the probability that if a solution is recorded within this time it will be the correct one. If the universe of discourse is now restricted to correctly solved items, the probability (P_S) that a particular correct solution will be returned within a period of t sec. after the moment the problem is presented will be a function both of the dynamics of the problem-solving process as such and also of P_C, for if $P_C \neq 1$ at time t then P_S must be modified, and if $P_C = 0$, P_S must be zero also. Let P_S be defined as the probability which would obtain if $P_C = 1$ for $t = \infty$. No comprehensive statement can be made about a person's ability to solve a problem which does not involve at least these three probabilities, that is, any attempt to measure 'intelligence' by mental-test methods should involve assessments of P_C, P_E and P_S.

No valid analysis of the experimental data can be made outside the range of difficulties defined by $D = 85$ and $D = 10$ (where D is as defined below) for reasons which will be discussed elsewhere. Within these limits, they strongly support the hypothesis that:

$$P_S = \int_0^t \frac{1}{\sigma_S\sqrt{2\pi}} \exp - (\log t - mD + S)^2/2\sigma_S^2 dt \quad (1)$$

$$P_C = 1 - \int_0^t \frac{1}{\sigma_C\sqrt{2\pi}} \exp (\log t - C)^2/2\sigma_C^2 dt \quad (2)$$

$$P_E = 1 - \int_0^D \frac{1}{\sigma_E\sqrt{2\pi}} \exp (D - E)^2/2\sigma_E^2 dD, \quad (3)$$

where σ_S, σ_C, σ_E all have the usual connotations for a normal distribution, D is the difficulty of the problem being considered, defined in the conventional but arbitrary fashion $D = [100 - R]$, and R is the percentage of an adult British population (unselected) who achieve success with the item; m is the slope

$d(\log t)/dD$, in the usual way. S, C and $\dot{E}$ are constants which define the subject's speed, continuance (a function of persistence) and solution–recognition–efficiency (see definition of P_E) within the test situation being studied.

If a problem is incorrectly solved, and if t_w is the time elapsing between the presentation of the problem and the recording of an incorrect solution, then:

$$P_w \text{ does not have the same form as } P_S, \qquad (4)$$

where P_w is the probability that the incorrect solution will be returned within a period t_w.

Equation (3) is of the same form as expressions suggested by Thorndike and Thurstone. So far as I know, (1) and (2) have not previously been advanced. The main interest of these results centres about (1), for there is very strong evidence that m and σ_S are identical for all the subjects who have so far been examined, not only within a particular test situation, but also between situations involving different degrees of motivation. $m = 0{\cdot}013$ (S.E.$_{\text{est.}} = 0{\cdot}0005$) and $\sigma_S = 0{\cdot}12$ (S.E.$_{\text{est.}} = 0{\cdot}005$), all values being in log-sec. units. The range of values of S encountered experimentally is such that as $D \rightarrow 0$ both m and σ_S must depart from these values. Such evidence as is available suggests that both parameters retain their values in the region $D > 85$. It seems probable that these two parameters can join Philpott's[2] fluctuation constants, p and T_0, bringing the number of true psychological constants up to four. There is presumptive, but not as yet conclusive, evidence that σ_C (1) is also a true constant.

It follows immediately from equations (1)–(4) that, when attempting to measure S, all the test items used should be easy and of identical difficulty, and that only items correctly solved can be used in calculating the score obtained. Existing methods of measuring mental speed ignore these requirements so completely that it seems justifiable to make this point even in a preliminary communication of this nature. Adherence to these principles has made possible the design of a speed-test which requires only some 15 min. to administer, and in connexion with which the concept of (statistical) 'reliability' can legitimately be used ($r_{11} \simeq 0{\cdot}9$). Equation (2) leads directly to a method of designing 'cognitive' tests in such a fashion that they can be scored for persistence as well as for the ability ostensibly under examination.

It is possible that σ_S results from the functioning of some kind of cerebral 'search' mechanism. For example, if the successful solution of a problem of difficulty D_b were to involve the bringing into relationship of b neural elements which had to be correctly selected in the right order from a pool of n elements, then we can postulate that for some time t_1 the search mechanism examines relationships involving less than b elements, so that no solution to a problem of difficulty D_b can ever occur during this time. At time $t_1 + \delta$ the first relationship involving b elements occurs, and relationships of this complexity continue to occur until all have been examined after time t_2. The suggestion is that σ_S is a function of the interval $(t_2 - t_1)$ and of the frequency with which correct solutions arise at different values of t within these limits, rather than of the error of determination of some value t_b which is the 'true' time for solution for all problems of difficulty D_b. The characteristics of a number of possible search mechanisms are now being examined in detail in the hope that the time-difficulty relationships of one of them will satisfy the requirements of equation (1), while at the same time being physiologically plausible. It is interesting to note that if the problem-solving process in any way resembles that suggested above, then item difficulty is a discontinuous variable, no values of D being possible between D_b and D_{b+1}.

This work has been carried out in the course of an investigation of methods of selecting students for universities which is sponsored by the Nuffield Foundation. Short papers presenting successive stages of the analysis were read before the Twelfth International Congress of Psychology[3] (Edinburgh 1948) and the British Psychological Society[4] (London 1950). A full report is being prepared for publication.

Male Sterile Plants by Chemical Treatment

It is well known that treatment with 'growth hormones' reduces the fertility of plants. Not only do the 'auxins' seem to be antagonistic to the initiation of flowering, but also they reduce the number of seeds that develop from treated flowers, or they may cause total sterility. This effect is used in blossom-thinning sprays and in the production of parthenocarpic fruits.

The reasons for the sterility induced by chemical treatment have not yet been thoroughly investigated. Recently, Moore[1] and Naylor[2] reported that maleic hydrazide, a plant-growth inhibitor, produces only male sterility in maize, whereas the female flowers remain fertile and set seed after pollination with pollen from untreated plants. A method of inducing male sterility leaving the female organs fertile by a simple chemical treatment would be of great importance for the production of hybrid seed not only with maize but even more so with many other cultivated plants, where emasculation and pollination by hand are prohibitive to the production of hybrid seed on a large commercial scale, or where this method is impossible for technical reasons such as smallness of reproductive organs. Also with many breeding problems, for example, with beet, carrots, rye, such a method could be very helpful.

Plants of Hawksbury and Cape Mountain Sweet water-melons were treated with various concentrations of 2,4-dichlorophenoxyacetic acid, tri-iodobenzoic acid and maleic hydrazide. The chemicals were applied, about a week before the first flowers opened, to all parts of the plants in a hill as a spray in aqueous solution with a wetting agent. Degree and duration of male sterility were checked by pollinating protected female flowers from untreated plants with pollen from the treated plant. The female flowers of the treated plants were left open for pollination by insects.

The checking for male sterility was started one to three weeks after treatment. Full male sterility for more than one week was found with the following treatments: 10 p.p.m. tri-iodobenzoic acid, applied every week; 50 p.p.m. tri-iodobenzoic acid, application repeated once after four weeks; 250 p.p.m. tri-iodobenzoic acid, applied once; 5 p.p.m. 2,4-dichlorophenoxyacetic acid, applied every week. The pollen of the male sterile plants showed various abnormalities: grains with more or less vacuolated plasma, small, shrivelled, empty grains, and in the variety Cape Mountain Sweet, often a high percentage of giant, unreduced grains. In sterile pollen these visible abnormalities amounted always to 20 or more per cent.

The female flowers which opened in all these treatments during the period of male sterility were at least partly fertile. As with untreated plants, not all the female flowers set fruit, and some fruits grew only to a quarter or a half the size of normal fruits, but with fully developed seeds. The best fruit set was found with the plants treated with 250 p.p.m. tri-iodobenzoic acid, a very poor set with the plants treated weekly with 5 p.p.m. 2,4-dichlorophenoxyacetic acid, but this treatment had generally also a very detrimental effect on the growth of the plant.

Lower concentration of 2,4-dichlorophenoxyacetic acid and tri-iodobenzoic acid did not produce full male sterility. Maleic hydrazide was used only in the concentrations 250 and 500 p.p.m. These concentrations caused only a short inhibition of the vegetative growth, after which the plants were found fully fertile.

Laibach and Kribben[3] succeeded in increasing the proportion of female flowers in cucumbers by treatment with α-naphthalene acetic acid and β-indolyl acetic acid. The suppression of all male flowers would be another way of producing purely female plants. If applied to young water-melon plants, tri-iodobenzoic acid produces a higher proportion of female flowers (in two cases the first flowers which opened on a plant were female, whereas on untreated plants only male flowers open for some days before the first female flower appears), but never suppressed the formation of male flowers entirely. More successful was the treatment of a wild *Citrullus vulgaris* plant in full bloom which had only male and hermaphroditic flowers. Before treatment, this plant had a proportion of 10·1 male to 1 hermaphroditic flower. From the thirteenth to the twenty-second day after treatment with 50 p.p.m. tri-iodobenzoic acid, this changed to 0·8 male to 1 hermaphroditic, and for two days only hermaphroditic flowers opened. (During this period the bisexual flowers were self-sterile, the open-pollinated flowers set fruit.) A similar behaviour was shown by a cucumber plant in the greenhouse (variety Early Fortune), which after treatment with 25 p.p.m. tri-iodobenzoic acid produced five male and seven female flowers over a period of five days, and during two days only female flowers. (The male flowers were sterile; one of the female flowers developed seed after pollination with pollen from an untreated plant.)

As most of the work on parthenocarpy by chemical treatment has been done with tomatoes, some additional experiments were made with this plant. The plants were grown in pots in the greenhouse and treated about a week before the first flowers opened. Sterility for about eight weeks was obtained with 25, 50 and 100 p.p.m. tri-iodobenzoic acid and 10, 25 and 50 p.p.m. 2,4-dichlorophenoxyacetic acid, whereas 50 p.p.m. naphthalene acetic acid and 500 p.p.m. maleic hydrazide induced sterility for only 10–14 days. Crosses with pollen from untreated plants showed that the ovules of plants treated with 25 and 50 p.p.m. tri-iodobenzoic acid are able to produce seed during the period of sterility. 2,4-Dichlorophenoxyacetic acid in the concentrations used inhibits growth and flower formation for several weeks and seems to impair also the fertility of the female organs; no definite conclusions on the female fertility of the tomato plants treated with this substance can be made at this stage. The microscopic examination of the sterile tomato pollen showed visible abnormalities of the grains, various degrees of vacuolization, or coagulation of the plasma, or a certain percentage of small, empty grains.

It has been shown that treatment with certain growth-regulating substances produces male sterility in cucurbitaceous plants and in tomatoes for periods of one to several weeks.

These investigations are being continued. A full report will be published elsewhere.

Detoxication of Hormone Herbicides by Soil Bacteria

The selective herbicides 2,4-dichlorophenoxyacetic acid (DCPA) and 2-methyl-4-chlorophenoxyacetic acid (MCPA) are known to undergo a gradual detoxication in soil due to biological agencies, and Audus[1,2] has recently reported the isolation of a bacterium capable of decomposing the former, which is apparently utilized as a source of carbon. In the course of work on herbicide detoxication in soil, we have succeeded in isolating two types of bacteria with similar properties from soil repeatedly treated with 2,4-dichlorophenoxyacetic acid. Pure cultures were readily obtained by plating from soil on an agar medium containing 0·10 per cent sodium salt of the acid as the sole source of carbon. The first organism (No. 1) grew abundantly in ordinary bacteriological media and was identified as *Flavobacterium aquatile* (Bergey[3]). The second (No. 2) bore some morphological resemblance to the organism studied by Audus —small, irregular, non-spore-forming, non-motile rods of a *Corynebacterium*-like appearance, but Gram-negative, sometimes with Gram-positive granules. It grew very feebly in ordinary media and showed no conspicuous biochemical activities; but on ammonium phosphate agar with 0·1–0·2 per cent sodium salt of 2,4-dichlorophenoxyacetic acid or 2-methyl-4-chlorophenoxyacetic acid it produced a slow but eventually quite vigorous, whitish and slimy growth. A mere trace of growth occurred on the basal medium without added organic matter. Glucose and glycerol were utilized very poorly; phenol, sodium benzoate and sodium salicylate not at all.

Measurements of the evolution of carbon dioxide from garden soil plus 0·01 per cent sodium salt of either acid, inoculated with cell suspensions of the two bacteria, showed that 50–100 per cent of the carbon added in the herbicides was liberated as carbon dioxide after two to three weeks at 25° C. After the experiment, tests with barley seedlings (percentage germination, and weight of sprouts) showed that the toxic effect of 2,4-dichlorophenoxyacetic acid had been completely abolished by both bacteria, and that of 2-methyl-4-chlorophenoxyacetic acid also by Bacterium No. 2. Cultures of both bacteria, when freshly isolated, also detoxified the former in solid (2 per cent) agar medium with ammonium phosphate as a source of nitrogen (see Table 1).

Table 1. INCUBATION 28 DAYS AT 25° C

Medium	Percentage germination of barley	Fresh weight per 100 sprouts of barley (gm.)
Agar + 0·005 *M* DCPA, sterile	9	0·22
„ inoculated with *F. aquatile*	98	6·28
„ inoculated with Bacterium No. 2	98	5·03
Sterile agar without DCPA.	99	6·63

Unlike Audus[1,2], we observed no significant detoxication by either organism in semi-solid (0·2 per cent) agar medium, or in soil extract.

After several transfers, *F. aquatile* grew very feebly on 2,4-dichlorophenoxyacetic acid but was still able to decompose this substance in sterile soil, like Bacterium No. 2, which also decomposed 2-methyl-4-chlorophenoxyacetic acid.

Table 2. GARDEN SOIL STERILIZED BY AUTOCLAVING AND INCUBATED AT 25° C. FOR FIFTEEN DAYS (WITH 2,4-DICHLOROPHENOXYACETIC ACID) OR FOR FOURTEEN DAYS (WITH 2-METHYL-4-CHLOROPHENOXYACETIC ACID)

Treatment	Percentage germination of barley	Fresh weight per 100 sprouts of barley (gm.)
Soil without addition, sterile	96	4·30
Soil + 0·01 per cent DCPA (sodium salt), sterile	47	0·79
„ inoculated with *F. aquatile*	98	4·31
„ inoculated with Bacterium No. 2	95	4·49
Soil without addition, sterile	96	4·86
Soil + 0·01 per cent MCPA, sterile	43	0·95
„ inoculated with Bacterium No. 2	95	4·64

In other experiments we obtained complete detoxication of 0·01 per cent 2,4-dichlorophenoxyacetic acid by *F. aquatile* in five days, but this organism was not active towards 2-methyl-4-chlorophenoxyacetic acid.

Two entirely different species of bacteria, one of which may be related to Audus's organism, are thus able to detoxify 2,4-dichlorophenoxyacetic acid, and one of them also 2-methyl-4-γ-chlorophenoxyacetic acid. The very feeble growth of the latter organism in all media except those containing the two herbicides suggests that it may be an induced mutant of some other soil bacterium which has become specialized in the utilization of a few cyclic compounds.

The results of our experiments will be published in detail elsewhere.

Root Parasites in Loranthaceæ

THE plant family Loranthaceæ (mistletoes, etc.) contains several hundred species, almost all partial parasitic shrubs growing on the branches of trees. The following species are terrestrial shrubs or trees: *Nuytsia floribunda* R.Br., of Western Australia, several South American species of *Gaiadendron* G. Don, and *Atkinsonia ligustrina* (A. Cunn. ex F. Muell.) F. Muell., which is known only from the Blue Mountains of New South Wales, where it occurs sporadically on dry, rocky ridges. This small group of terrestrial species is stated by various authors (for example, Macgregor Skene[1]; Moore and Betche[2]) to be non-parasitic; but Herbert[3] has shown that *Nuytsia floribunda* is a root parasite, as was indeed conjectured by Harvey[4] in 1854. It attacks a wide range of hosts, including both native and introduced species. *Atkinsonia ligustrina* has now been investigated at Woodford, N.S.W., and shown to form haustoria attached to the roots of several host species, including *Acacia intertexta* Sieb., *Platysace linearifolia* (Cav.) Norman (syn. *Trachymene linearis* Spreng.) and the narrow-leaved form of *Leptospermum attenuatum* Sm. Thus, of the terrestrial Loranthaceæ, only the species of *Gaiadendron* (with which *Atkinsonia ligustrina* was associated systematically by Bentham and Hooker[5] and by Engler[6]) are not known to be parasitic. It would not be surprising if they too should prove to be root parasites.

It is hoped to publish elsewhere some details of the relations between *Atkinsonia* and its host plants.

Observation of Egg-laying under Water of the Aerial Insect *Hydropsyche angustipennis* (Curtis) (Trichoptera)

DOUBT has existed about the mode of egg-laying in certain caddis flies, especially those the eggs of which are found under water in flat sheets cemented to the lower surface of stones. Accounts for most of these species are based on indirect evidence and incomplete observation. Consequently the following direct observation on the entry of *Hydropsyche angustipennis* into a watery medium may be of interest.

Unlike many Trichoptera, this caddis fly is not crepuscular, and on a sunny June afternoon an imago was observed alighting on a stone projecting above the water surface in an upland stream at Craigton, near Glasgow. She remained there for some moments with her antennæ bending over so that the tips were in the water, then suddenly flew up two or three feet, zig-zagged rapidly over the stream for a few yards and dived vertically down into the water. Air carried down on the hairy, folded wings gave her a silvery appearance as she swam rapidly straight to the lower surface of an inclined submerged stone. The stream here was about 9 cm. deep and the current velocity less than 15 cm. per second. These observations tend to confirm Wilson's remarks on *Stenopsyche* as recorded by McLachlan[1]. When, after a few seconds, the stone referred to above was raised and the female captured *in situ*, it was found that she had already deposited some eggs in a flat sheet with transparent, colourless cement between them. The captured female was kept in captivity, surviving for two days during which she again entered the water and laid some 460 eggs while continuously submerged for 37 min. Details of these observations will be given in a later paper.

The method of respiration enabling this aerial insect to remain under water for so long while performing strenuous activities requires further investigation. Possibly air carried down on the hairy body surface functions as a physical gill. It is doubtful whether a plastron is formed in caddis flies; it has only been demonstrated in certain aquatic beetles and in the bug *Aphelocheirus*[2].

In *H. angustipennis* there are no striking morphological adaptations for swimming such as have been described by McLachlan as indicative of possible swimming powers in *Amphipsyche*[3]. The female imago of *H. angustipennis* is bigger than the male; but relative to body-size there is little difference in the limbs of the two sexes. A fringe of hairs found only on the mesothoracic tarsi of the female might possibly aid in swimming.

The observations noted above may be significant in considering the ecological distribution and population density of this species; for example, the speed of the current may affect the ability of the female to reach suitable sites for oviposition and become a limiting factor in determining distribution.

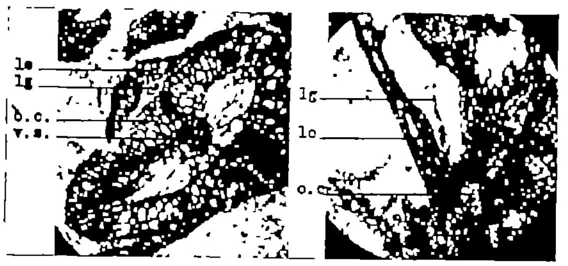
A Ligulate Pteridophyte from the Lower Coal Measures of Bacup, Lancashire

THE specimen to be described is a coal-ball petrifaction from the Old Meadows Pit, Bacup, Lancashire, and consists of a main axis, which followed a very sinuous course in the coal-ball. Of this axis the tissues of the outer cortex and the stelar xylem only are preserved, there being a wide space between the outer cortex and the central stele.

Interest in the specimen was stimulated by the observation that curious appendages were borne on the main axis, these appendages being very similar to Stigmarian rootlets but bearing ligulate leaves.

The vascular cylinder of the main axis, like the whole axis, followed a sinuous course in the coal-ball and only xylem tissue is preserved. The xylem consists of a solid core of primary xylem and some secondary xylem. The primary xylem is of scalariform tracheids only, with no recognizable protoxylem, although the central elements are smaller than the peripheral ones. In transverse section the secondary xylem appears as wedges of regularly arranged elements separated by wide primary medullary rays, the tissues of which are not preserved, but in each ray a xylem trace passes out from the primary xylem. These rays and xylem traces are clearly seen in longitudinal sections, and in longitudinal tangential sections the secondary xylem presents the appearance of an anastomosing network of elements with a xylem trace in the centre of each mesh. The secondary xylem elements are tracheidal in nature, show scalariform thickening, but are narrower and very much shorter than the primary xylem elements. Where preservation is sufficiently good, both primary and secondary xylem elements show the fine threads of thickening extending in a vertical direction between the transverse bars of thickening, a feature characteristic of the xylem of Lepidodendroid plants. The stelar xylem as a whole measures 2·5–3·0 mm. in diameter and the primary xylem 1·25–1·5 mm. in diameter.



(*A*) (*B*)

A, Transverse section leafy appendage. *B*, longitudinal section outer tissues of leafy appendage (× 25). *le*, leaf, *lg*, ligule, *o.c*, outer cortex, *v.s.*, vascular strand

The preserved remains of the cortex of the main axis, which is outer cortex, may be divided into two zones. The outer zone is part of the original outer cortex, while the inner zone, consisting of regular thin-walled cells, is phelloderm developed centripetally from a phellogen situated just inside the outer zone. No evidence can be found of leaves being borne on the main axis; but embedded in its outer cortex are the bases of the curious leafy appendages, which thus appear to arise endogenously.

The leafy appendages are bud-like structures, 1·5 mm. average diameter, with monarch xylem of rarely more than six tracheids. The tissue immediately outside the xylem is badly preserved and its nature is indeterminate (Fig. *A*). Between the monarch vascular strand and the outer cortex in the better preserved examples are strands of cells forming trabeculæ. Borne on these appendages are leaves, 3·3 mm. long, 0·6 mm. wide and 0·15 mm. thick at the base. These leaves possess neither vascular tissue nor stomata, and they are definitely ligulate (Figs. *A* and *B*). The ligule is 0·33 mm. long, four or five cells wide at the base and two cells thick, except at the tip.

Transverse and longitudinal sections of the cortex of the main axis show these appendage origins as cylindrical masses of parenchymatous tissue, in the centre of each of which is a very small vascular strand. Passing outwards through the cortex the vascular strand becomes better developed, but the parenchymatous cells around it become disorganized except for the trabeculæ. After careful searching it has been found impossible to show any connexion between the xylem of these appendages and the xylem of the traces which depart from the periphery of the primary xylem of the main axis.

The leafy appendages raise very interesting points. They may represent fully developed adult structure or they may be young stages of an arborescent type, or they may be organs of vegetative propagation.

In some respects the specimen is reminiscent of *Stigmaria bacupensis* Scott et Lang[1]; for example, in size. The diameter of the main axis, of the stele and of the appendages are all of the same order as in *S. bacupensis*; but this new specimen differs from *S. bacupensis* in the following features: (1) the protostele has no recognizable protoxylem; (2) the cortex of the main axis has quite a different structure; (3) the outer cortex of the appendages differs from the outer cortex structure of the rootlets of *S. bacupensis*; (4) the appendages bear leaves.

The structural features of this new specimen suggest a Stigmarian axis bearing appendages rather similar to Stigmarian rootlets; but the appendages of this new plant bear leaves and the leaves bear ligules. It may be that this new specimen indicates that the so-called rootlets of *Stigmaria* are really of stem nature. In this connexion it is interesting to note that in the same coal-ball and in close proximity to the specimen just described are remains of outer cortical tissues which are identical in structure with those of the new specimen, but this cortex bears ordinary Stigmarian rootlets and not leafy appendages.

Supra-vital Staining of Striated Muscle with Tetrazolium Compounds

The fact that a nearly colourless solution of 2 : 3 : 5 triphenyl tetrazolium chloride (tetrazolium salt) is reduced to a red formazan in contact with living tissue has been recognized for some time. This has been used in testing for viability and also for staining tissues; but detailed descriptions of the colour distribution within tissues are lacking. Since the red colour is due to reduction of the agent, the colour distribution should offer some evidence as to the intracellular distribution of reducing groups.

In the present work, small strips of striated muscle from freshly killed mice have been teased out in a 0·1 per cent solution of tetrazolium in normal saline or Ringer–Locke solution. The preparations were mounted under cover slips, ringed with a 'Vaseline'-wax mixture and examined immediately. The red colour appears within 3½ min. and continues to intensify until all the muscle fibres are deeply stained. Under the high-power microscope, the colour is seen to be concentrated in transverse bands in the muscle, while the intervening bands are but faintly stained; a narrow band of intermediate staining intensity traverses the centre of the faint band. This is illustrated in Fig. 1. Apart from the coloration, the appearance is very similar to that seen in a phase-contrast picture (cf. Fig. 2).

Experiments with the related compounds 2,2′-(*p*-diphenylene)-*bis*(3,5 diphenyl tetrazolium chloride) (neotetrazolium) and 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyl tetrazolium chloride (iodotetrazolium) have given similar results. In the case of neotetrazolium, the reduction colour is a deep purple-black, and in some preparations the longitudinal striæ of the muscle fibres have also appeared. The distinctive distribution of the colour is strongly suggestive of a similar distribution of reducing groups within the muscle fibre. Since the overall picture remains the same despite intensification of the colour, it appears unlikely that the result achieved is dependent upon differential rates of infiltration of the agent into the various portions of the muscle fibre.

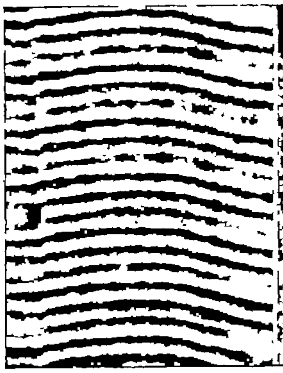

Fig. 1. Striated muscle stained with tetrazolium. (× 1,500)

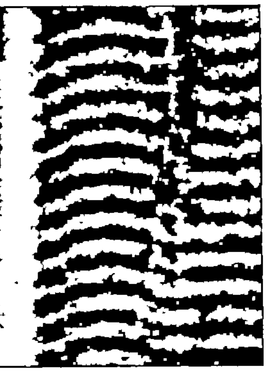

Fig. 2. Striated muscle, unstained (phase contrast. × 1,500)

It appears, then, that these salts not only provide a useful tool for histological demonstration, but may also offer evidence as to the distribution of cellular components.

Noradrenaline and Accessory Chromaffin Tissue

Fulk and Macleod[1] showed that the retro-peritoneal tissue of many mammals contains a material which, like extracts of the suprarenal glands, produces inhibition of the isolated rabbit intestine and excitation of the isolated rabbit uterus. Using histological methods, Wislocki[2] confirmed that there is abdominal chromaffin tissue in these animals. Whereas Mulon[3] showed that the chromaffin tissue in the carotid bodies of horses contains a pressor substance, Fulk and Macleod[1] failed to obtain any sympathomimetic substance in extracts of the thoracic aorta (containing the chromaffin tissue of the cardioaortic bodies). Recently, West, Shepherd and Hunter[4] reported that the collection of chromaffin tissue known in babies as the organs of Zuckerkandl contains large amounts of noradrenaline. The paraganglia are situated along the aorta near the origin of the inferior mesenteric artery. We have therefore attempted (*a*) to confirm that a sympathomimetic substance is present in accessory chromaffin tissue of animals, and (*b*) to identify such a substance by biological and chromatographic methods[4].

The results shown in the accompanying table indicate that large amounts of noradrenaline may be found in the retro-peritoneal tissue of young dogs, rabbits, guinea pigs and cats, and in certain cases

BROADCASTING AND TELEVISION IN GREAT BRITAIN

THE Government's Memorandum on the Report of the Broadcasting Committee*, which was published as a White Paper on May 15, dropped one of the proposals of its predecessors which had been much criticized as likely to endanger the independence of the British Broadcasting Corporation and expose it to pressure from local sectional if not party political interests. It included three new proposals, however, which have met with strong independent criticism cutting right across political party lines. Nevertheless, following debates in the House of Lords on May 21 and 26, the White Paper was approved in the House of Commons on June 11 after a debate which left considerable room for doubt whether that approval would, in fact, have been obtained on a free vote. Afterwards, on June 19, the Prime Minister announced that the proposal for a new method of electing the governors of the British Broadcasting Corporation would be abandoned, and hopes were raised that the Government would no longer insist on making the question of broadcasting policy a party issue. The new licence and agreement of the British Broadcasting Corporation with the Postmaster General, published on June 13, were, however, adopted on June 23 after a debate in which the House of Commons again divided on party lines, and a new Royal Charter for the British Broadcasting Corporation was promulgated by Order in Council on June 24.

No matter who was mainly responsible, making broadcasting policy a party issue will be generally regretted by that large volume of responsible opinion which has followed the discussion of the future of British broadcasting since the Beveridge Committee reported early last year. The recent debates in Parliament made it clear that on all the main issues the division of opinion does not lie on party lines. On balance, the general trend of opinion seems to be in favour of continuing the present arrangements broadly on the lines recommended by the Beveridge Committee, without prejudice to the issue of monopoly, or to the exact form which regionalism or decentralization might take owing to technical development in the next few years. Indeed, the discussions in Parliament were marked by the same open-mindedness on the question of monopoly as has characterized most public discussions on broadcasting policy during the past two years, even on the part of those who expressed the greatest admiration for the achievements and character of the British Broadcasting Corporation. There is a widespread distrust of the policy of continuing indefinitely to give to any one body the responsibility for an instrument which can influence so powerfully for good or evil the minds of men and women.

The debates scarcely did justice to the extent to which this sense of social responsibility marks discussion of this question outside the Houses of Parliament, particularly where television is concerned. It is this sense of social responsibility with regard to something the significance of which is at present only dimly appreciated that is behind the distrust with which anything like 'sponsored' or commercial broadcasting is widely regarded. It is considered unwise to place such powers anywhere but in the hands of a body with high standards of public service to maintain.

---

* Broadcasting: Memorandum on the Report of the Broadcasting Committee, 1949. (Cmd. 8550.) Pp. 10. (London: H.M. Stationery Office, 1952.) 6d. net.

To this feeling the Government has done less than justice. Moreover, there is some room for doubt as to whether developments in television or in sound broadcasting, for example, in very-high-frequency broadcasting, need be quite so delayed by stringencies in capital resources, labour or materials as the White Paper suggests. The Government's inept handling of the whole matter has itself encouraged what are possibly quite unfounded doubts of its sincerity. By committing itself to a particular way of ending monopoly when there is a general readiness to consider impartially whether there are alternatives which can offer wider choice to the viewer or listener and at the same time maintain the present high standards of public service, it has exposed itself needlessly to the charges of yielding to sectional interests in matters which should be determined by technical inquiry and the public interest. It might be added that the Government's own proposals, so far as the British Broadcasting Corporation is concerned, may be expected, as indeed were those of Mr. Attlee's Government, to strengthen, through the inhibitions and restrictions they propose, the ossification which is almost inherent in any large organization with the passage of time.

Technical factors are a main reason for regretting the Government's determination to make broadcasting a party issue. The decision, moreover, does not assist a satisfactory solution of the other main problems—regionalism and the method of appointing governors. Here again an agreed and impartial solution demands more searching inquiry and constructive thought than was manifest in the Parliamentary debates. Disregarding speeches, such as those of the Lord Chancellor, which gave colour to the view that the White Paper represents a surrender to commercial interests or small pressure groups of extremists, even such reasonable and lucid speeches as those of Sir David Maxwell Fyfe in opening the debate on June 11 were sometimes a little naive. The Government cannot claim, without discrediting itself, that it has had only a few weeks to consider the future pattern of broadcasting before the Charter and licence of the B.B.C. expired. It has been obvious since the Broadcasting Committee issued its report in January 1951 that this was an issue on which any government in power would have to make up its mind before the end of the year.

The immediate need is for all who realize how large an influence both sound broadcasting and television have come to play in the lives and minds of the community to seek to prevent any further surrender to such political or commercial interests and to work out both the technical and the administrative measures essential to prevent either the lowering of standards or the abuse of power. The real questions are not brought out clearly in the Government's White Paper any more than in that of its predecessor last July. Even Sir David Maxwell Fyfe's careful summary of the arguments for and against monopoly in his speech on June 11 gave insufficient weight to the extent to which the question of 'sponsored' programmes has widened out to the complex question of whether monopoly is the best form of organization for broadcasting. It is assumed too readily that the only alternative to the sponsoring of programmes by advertisers is monopoly, and there have been few signs of any disposition to enter on the hard thought which must precede the evolution of any new system which could avoid the dangers and disadvantages of either the present monopoly or sponsoring by advertisers.

That, however, is the immediate task. The Government's proposal to permit some element of competition in the expanding field of television, when calls on capital resources make this feasible, and the promise that Parliament should in any event have an opportunity of considering, before the licensing of the first station, the terms and conditions under which competitive television would operate, will at least give further time for reflexion. The Government's own memorandum admits that it would be necessary to introduce safeguards against possible abuses and that a controlling body would be required for this purpose; indeed, the conditions proposed are, in fact, so onerous that it is difficult to imagine anyone risking capital on them, and that they have aroused such alarm is rather a measure of the extent to which the Government's good faith is distrusted.

On this point two further observations may here be made. First, that distrust might well have been less had the Government proposed to take the first step towards competition in broadcasting by letting broadcasters compete in public service. There would then have been no reason for the suspicion that business interests rather than the desire to afford the viewing public some choice of programmes has been the deciding factor. The second point is that some technical opinion is strongly opposed to any such distinction being made between television and sound broadcasting, holding that they should be encouraged to grow together, instead of being kept apart. This argument may well gain further support if sound broadcasting and television are considered as cultural factors and even as determinants in the social life and thought of the nation. That aspect, so powerfully emphasized in a recent report by Robert Silvey, head of B.B.C. Audience Research, published in the *B.B.C. Quarterly*, received less than its due notice in the debates, apart from incidental reference by Mr. Herbert Morrison. Mr. Silvey's picture of the way in which television is spreading rapidly among the lower-income groups of Britain, who now hold much the larger proportion of viewers, and its effect on family habits and leisure, emphasize what an important social factor television has already become and what grave dangers could attend its abuse by any sectional or commercial interest.

ABSOLUTE AMOUNTS (μGM.) OF ADRENALINE AND NORADRENALINE IN ANIMAL TISSUES

Species	Age	No. of expts.	Suprarenals		Retro-peritoneal tissue	
			Adrenaline	Noradrenaline	Adrenaline	Noradrenaline
Rabbit	*In utero*	6	0	4	0	4
	1 hr.	8	4	5	0	12
	1 day	4	0	7	0	5
	2 days	10	5	5	0	5
	4 days	6	10	2	0	2
	Adult	8	92	0	0	0
Dog	1 day	1	10	10	0	15
	6 days	1	45	20	0	12
	9 days	1	50	25	0	10
	Adult	1	500	200	0	0
Cat	*In utero*	4	3	10	0	3
	12 hr.	4	16	70	0	25
	1 day	2	20	70	0	10
	3 days	2	40	60	0	5
	Adult	10	120	80	0	0
Guinea pig	*In utero*	2	0	5	0	10
	1 hr.	2	5	5	0	10
	2 days	4	20	5	0	3
	Adult	8	71	0	0	0

this amount exceeds that found in the suprarenal glands. These additional chromaffin structures must therefore perform some autonomic function early in life—perhaps the maintenance of blood pressure. As the animal grows older and the suprarenal medulla matures, so the amine content of this accessory tissue declines. On the other hand, extracts of the carotid bodies and of the aortic bodies of rabbits, cats and guinea pigs did not yield any sympathomimetic material. This may not be so surprising, since chromaffin tissue is not necessary for the production of adrenaline and noradrenaline. Precursors of noradrenaline, such as hydroxytyramine and dihydroxyphenylalanine, were not detected in any of the above extracts.

Effect of Cortisone on the Blood Pressure of Normal Rats

THE importance of the adrenal cortex in the regulation of the blood pressure has recently been emphasized by several authors. The effect of prolonged treatment with high doses of cortisone on the rat's blood pressure was therefore investigated.

Seventy-two male white rats weighing 144 ± 3 gm. were fed on a synthetic diet containing 30 per cent proteins, 56 per cent carbohydrates, 10 per cent lipids, 4 per cent McCollum salt mixture and supplements of vitamins and lipotropic factors; water was allowed *ad libitum*. Forty-six rats were injected subcutaneously with 5 mgm. of cortisone acetate ('Cortone', Merck) daily for twelve days; 26 controls received injections of 0·9 per cent sodium chloride solution. The blood pressure was measured by the method of Friedman and Freed[1]; in ten experimental animals and in ten controls the electroencephalogram was taken (lead 2) and their plasma and blood volumes were determined after a fast of 12 hr., using Evans blue according to the method of Wang and Hegsted[2].

The mean blood pressure of the controls was 119 ± 3·5 mm. mercury at the beginning of the experiment; after twelve days the value was practically unchanged (121 ± 4 mm. mercury). In the cortisone-treated rats the blood pressure increased from the initial value of 115 ± 3 mm. mercury to 140 ± 5 mm. after twelve days of treatment. The difference is statistically significant ($P < 0{\cdot}01$). No definite modification of the electroencephalogram was found, except a significant increase of the heart-rate in the cortisone group (440 ± 15 beats per min. against 340 ± 11 in the controls).

At the end of the experiment, plasma and blood volumes were respectively 3·6 ± 0·2 c.c. and 6·8 ± 0·3 c.c. in the controls and 3·5 ± 0·4 c.c. and 6·6 ± 0·8 c.c. in the cortisone-treated animals (values referred to 100 gm. final weight). The weight of the heart and of the kidney was increased in the cortisone group, when referred to 100 gm. final body-weight, but remained unchanged when referred to 100 gm. initial body-weight. Histological examinations failed to show arterial lesions in the kidneys and the heart in either of the two groups.

Our observations suggest that large doses of cortisone given to normal rats fed on a balanced diet and with a normal intake of sodium chloride have a hypertensive effect, which seems to be accompanied by an increase of the heart-rate. It is not associated with changes of the blood volumes or with vascular lesions in the kidney.

A Unit of Wave-number

A YEAR ago[1], names suggested for the unit 'cm.$^{-1}$' were permicron, Rydberg and Balmer. In a recent review[2] of "Modern Interferometers", Prof. W. F. Meggers advocates 'Kayser'. Where early workers used the reciprocal of the wave-length in air, H. Kayser recognized that in complex spectra the wave-length in vacuum is essential, and so gave to 'cm.$^{-1}$' its proper definition. Moreover, he compiled the tables still used in the conversion. These arguments are convincing; the more so as Rydberg is commemorated by a constant and Balmer by a series, while K is here a more convenient symbol than R.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, July 7

ROYAL SOCIETY OF EDINBURGH (at 24 George Street, Edinburgh), at 4.30 p.m.—Prof. James Kendall, F.R.S.: "The First Chemical Society, the First Chemical Journal and the Chemical Revolution".

Monday, July 7—Saturday, July 12

INTERNATIONAL DIABETES FEDERATION (at Leyden, the Netherlands)—First International Congress.

MINISTRY OF FUEL AND POWER (at the Safety in Mines Research Establishment, Buxton).—Seventh International Conference of Directors of Safety in Mines Research.

Thursday, July 10—Friday, July 11

PHYSICAL SOCIETY (at Glasgow)—Summer Meeting.

Friday, July 11

UNIVERSITY OF LONDON (in the Clinical Theatre, Middlesex Hospital, Mortimer Street, London, W.1), at 5.30 p.m.—Prof. L. T. Samuels (Utah): "Enzymes Involved in the Synthesis of the Steroid Hormone".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN THE DEPARTMENT OF PHARMACEUTICS—The Clerk to the Council, School of Pharmacy, 17 Bloomsbury Square, London, W.C.1 (July 10).

BERRIDGE STUDENTSHIP IN PHYSIOLOGY as applied to public health—The Registrar, King's College, Strand, London, W.C.2 (July 11).

ASSISTANT (Grade B) to teach PURE MATHEMATICS to Intermediate Degree and PRACTICAL MATHEMATICS to A1 level, at the Rutherford College of Technology—The Director of Education, City Education Office, Northumberland Road, Newcastle-upon-Tyne 1 (July 12).

ASSISTANT LECTURER (temporary) IN BIOCHEMISTRY—The Registrar, The University, Sheffield (July 12).

PHYSICIST (with an honours degree in physics) to the Radiotherapeutic Department—The Group Secretary, Ipswich Group Hospital Management Committee, Anglesea Road, Ipswich (July 12).

SCIENTIFIC OFFICER (with a first-class or a good second-class honours degree in either physics or mechanical sciences) at the Agricultural Research Council's Unit of Soil Physics at Cambridge—The Secretary, Agricultural Research Council, 15 Regent Street, London, S.W.1 (July 12).

LECTURER IN CIVIL ENGINEERING at University College, Dundee—The Secretary, The University, St. Andrews (July 15).

GRADUATE ASSISTANT IN STATISTICS, for teaching, consultation and research in statistical science and biometry—The Lecturer in the Design and Analysis of Scientific Experiment, 6 Keble Road, Oxford (July 18).

READER IN EXPERIMENTAL FLUID MOTION AND DIRECTOR OF THE LABORATORY—The Registrar, The University, Manchester 13 (July 21).

CHAIR OF BACTERIOLOGY in the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (July 26).

DEMONSTRATORS (2, with qualifications in microbiology, biochemistry, or related subjects) IN THE DEPARTMENT OF MICROBIOLOGY—The Professor of Microbiology, The University, Reading (July 26).

HEAD OF THE CHEMISTRY LABORATORIES at the Central Research Establishment, Stoke Orchard, Cheltenham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/490 (July 26).

LECTURER IN ELECTRICAL ENGINEERING (with special reference to electrical machines and heavy current engineering)—The Secretary, University College, Gower Street, London, W.C.1 (July 28).

LECTURER IN MECHANICAL ENGINEERING at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (July 31).

PROFESSOR OF APPLIED MATHEMATICS in the University of the Witwatersrand, Johannesburg—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (July 31).

VENTILATING ENGINEER in the Naval Construction Department of the Admiralty, Bath—The Ministry of Labour and National Service, Technical and Scientific Register, 26 King Street, London, S.W.1 (July 31).

TECHNICAL OFFICER (with a university degree in science with botany as major subject, or diploma of agricultural college, or equivalent qualifications; experience in cytological techniques essential) IN THE DIVISION OF PLANT INDUSTRY, Canberra, to assist the Chief of the Division and other officers engaged in cytological investigations—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3883 (August 9).

CHAIR OF ARCHITECTURAL SCIENCE in the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 11).

DEPUTY PRINCIPAL INSPECTOR (in London) OF MECHANICAL ENGINEERING IN MINES AND QUARRIES, an INSPECTOR (in London) OF MECHANICAL ENGINEERING IN MINES AND QUARRIES, and INSPECTORS (5, in the Provinces) OF MINES AND QUARRIES—The Civil Service Commission, Scientific Branch, 7th Floor, Trinidad House, Old Burlington Street, London, W.1, quoting S.4153/52 (August 13).

CHAIR OF MATHEMATICS in University College, Dundee—The Secretary, The University, St. Andrews (August 15).

GEOPHYSICAL PROSPECTING OFFICER (with a degree in geology, and preferably with training or experience in geophysical prospecting methods) IN THE IRRIGATION DEPARTMENT, Southern Rhodesia—The Secretary, Rhodesia House, 429 Strand, London, W.C.2 (August 15).

LECTURER IN PSYCHOLOGY at Canterbury University College, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

LECTURER IN ZOOLOGY at Auckland University College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

SENIOR LECTURER IN PHILOSOPHY at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

LECTURER IN AGRICULTURAL ENGINEERING at Canterbury Agricultural College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 16).

CHAIR OF BOTANY in the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 30).

LECTURER (Chief Lecturer or Senior Lecturer grade) IN VETERINARY PATHOLOGY at the University of Queensland—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 31).

EDWARD A. DEEDS SENIOR FELLOWSHIP for research in physical science, viz., engineering, metallurgy, chemistry, physics, mathematical physics, or any cognate subject—The Secretary, University College, Dundee (September 1).

CHAIR OF APPLIED MATHEMATICS—The Registrar, University College, Exeter.

DEMONSTRATOR IN THE DEPARTMENT OF ENGINEERING—The Secretary and Registrar, The University, Southampton.

LECTURER and an ASSISTANT LECTURER IN CHEMISTRY—The Secretary, Royal Technical College, Glasgow.

MECHANICAL ENGINEER (Road Plant) IN THE PUBLIC WORKS DEPARTMENT, Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, quoting 'M/H Roads 1806'.

PHYSICIST (with a university degree in physics, or equivalent qualification, and an interest in experimental work on plant in actual operation) for research in Sheffield on methods of measurement and control of metallurgical furnaces—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1.

PRINCIPAL RESEARCH CHEMIST in the Division of Atomic Energy (Production), Windscale Works, Sellafield, to lead a section engaged on applied research work on a wide range of problems associated with the development of atomic energy (mainly in the field of inorganic and physical chemistry)—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting Ref. 347.

RESEARCH FELLOWSHIP IN MECHANICAL ENGINEERING—The Registrar, The University, Nottingham.

TECHNICAL ASSISTANT IN THE FUEL SECTION of the Plant Engineering Division in London; the work initially will be largely in connexion with the utilization, instrumentation, and design of furnaces, and with operational studies involving the heating and cooling of steel ingots—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting 'Fuel'.

This impression is confirmed by the admirable account of British broadcasting and television contained in Mr. Gorham's recent book, "Broadcasting and Television since 1900"*. This book, which should be read by everyone who desires to follow the present discussion on the future of British broadcasting, should correct many current illusions about the aloofness of the British Broadcasting Corporation and its failure to respond to public opinion. Implicitly, rather than explicitly, Mr. Gorham, in an eminently fair and readable book, shows the dangers inherent in the continuance of the broadcasting monopoly; but his book disposes of some of the wilder charges that protagonists of sponsored broadcasting have levelled against the British Broadcasting Corporation in the recent debates.

The book is important for another reason. It does not merely emphasize the moral issue, which Lord Reith stressed in his impressive speech in opening the debate in the House of Lords, and show clearly why the whole question of broadcasting should be treated in the same way and on the same plane as questions of education and other matters which profoundly influence the life and thought of whole communities; it also indicates clearly the right questions to be asked before we can hope to arrive at a considered policy and give it expression in a carefully worked out scheme. Such a scheme and policy the Government cannot yet claim to have laid before Parliament. Of some of the issues it appears to be only half aware. It agrees with the views of its predecessor as to educational broadcasting, without apparently appreciating the implication of this for any proposal to introduce an element in which public service is not to be the first and dominant consideration. Nor does it see, like Lord Waverley, in television an instrument of immense power, the social and economic implications of which are as yet but dimly appreciated. Without such a scheme, it is proposed, instead of keeping television and broadcasting in the hands of people whose sole purpose is to serve the public interest, to disturb a system which has served, and is admitted still to be serving, the country well.

Some of the speakers in Parliament, it is true, showed awareness of these questions, which should be answered before we decide how or even whether we should introduce competition. Lord Waleran, for example, pointed out that Germany, Italy and other countries, with or without a State monopoly, have overcome the wave-length problem by installing scores of very-high-frequency stations, whereas in Britain this is still experimental. Several speakers in the debates seemed no less conscious than Mr. Gorham of the backwardness of the B.B.C. in some respects during the post-war years, while other countries had made swift advances in technique.

These technical problems, however, appeared to be overlaid by the political aspects in the debate in Parliament, although they should be the decisive factors in determining the lines of development in the future. Nor were even the economic factors fully examined. Although the case for sponsored television rests largely on the assumption that it will bring in a contribution to broadcasting revenue which would otherwise be unobtainable, no one appeared to point out that the consumer ultimately pays in the increased cost of the advertised goods he buys, or to suggest any attempt to ascertain the amount of revenue which might be obtained. It was emphasized in the Commons debate that sponsored broadcasting is in effect subsidized broadcasting. Few besides Lord Samuel, Lord Hailsham and Lord Listowel challenged the proposal in both the present and last year's White Paper to raid the B.B.C.'s licence revenue. Lord Hailsham, however, showed the muddle into which this proposal leads, and Lord Kenswood gave a broad hint that an attempt should be made to discover whether the licence-holder would be prepared to pay a higher licence fee either to permit capital development or for improved television programmes before holding up indefinitely capital developments in television.

These are only some of the questions suggested by Mr. Gorham's book which are ignored in the White Paper and only cursorily examined, if at all, in these debates. None the less, while a free vote in the House of Commons might have gone against the Government's proposals, there was a widespread readiness to consider the question of monopoly with open minds, and no disposition to copy slavishly either the American or any other competitive system with the B.B.C. There was a general confidence that we should be capable of devising a British system which, whether or not it includes sponsoring, would supply, by healthy emulation in public service, the alternative programmes that are rightly demanded, competitively stimulate technical advance, and provide the necessary funds and opportunity for expression of regional and minority aspirations without debasing the standards of broadcasting of which Great Britain is rightly proud.

The debates in Parliament centred largely around the monopoly issue and sponsored broadcasting; the latter in particular, coupled with the Government's insistence on a party vote, tended to divert attention from one of the fundamental objections to the existing monopoly—that of a single employer. That aspect was dismissed rather summarily, and the proposals of the White Paper, particularly in regard to the regional councils, are unlikely to help the staff appreciably. It was made clear in the debates that the proposal by which the broadcasting councils will be responsible for the appointment of staff wholly employed in connexion with the Home Service programmes for which they are responsible is disliked by the B.B.C. staff, and the proposal was also criticized as administratively untidy if not unworkable.

Apart from the objection to this particular proposal on the ground of administrative efficiency, it can be criticized as a surrender to self-conscious and extreme nationalism, which might give too much scope for enthusiastic minorities to impose their tastes on the majority of their countrymen. More important, it may block the way for much sounder federal developments of the type advocated by Prof.

* Broadcasting and Television since 1900. By Maurice Gorham. Pp. 274. (London: Andrew Dakers, Ltd., 1952.) 18s. net.

Coatman. Decentralization such as he suggests, coupled with the possibilities which developments in very-high-frequency broadcasting have already put within our reach, should be able to satisfy all legitimate regional and cultural aspirations without detriment to the efficiency or the standards of the British Broadcasting Corporation.

For the rest, the new charter and licence provide for the B.B.C. to continue broadly on the existing basis. On the technical aspects of television, the Government will continue to seek advice from an advisory committee concerned with the development of television generally, and this advisory committee will also be asked to consider the best methods of introducing higher-frequency sound broadcasting, including the form of modulation to be adopted, on which consultation with the radio industry will be essential. The White Paper also points out that the establishment of new television services would require new stations and their ancillary services, such as studios, and that the radio industry must be advised as soon as possible in order to enable them to design and produce adaptors for existing television sets and new receivers capable of picking up either the B.B.C. programmes or those on other frequencies.

In this White Paper the Government accepts the view that, for many years, limitations on capital investment have prevented the B.B.C. from developing television in certain areas and from introducing very-high-frequency sound broadcasting. The latter view is not entirely accepted in the Beveridge Report, which included a memorandum on the subject by Mr. Geoffrey Crowther and Sir Robert Watson-Watt, and appears also to be disputed by Prof. Coatman when last year he pressed the Government to publish the report on very-high-frequency broadcasting submitted to the Postmaster General by the B.B.C. The Government considers that the B.B.C. has a continuing obligation to provide adequate national broadcasting services throughout the United Kingdom, and states that fulfilment of this policy must have first claim when labour and materials become available. Passages in the debate suggest that, where high-frequency broadcasting is concerned, neither finance nor materials need provide quite the obstacle to advance that is suggested, and Parliament seems to have missed in these debates an opportunity of insisting that the public should be given sufficient information for scientific men and technologists to form an independent opinion on this matter. As Prof. Coatman pointed out, it should not be left to confidential negotiation between the B.B.C. and the Postmaster General.

The most significant criticism of the proposals outlined in the Government's White Paper is that it shows insufficient imagination or sense of public responsibility for the immense power of sound broadcasting, and the possibly even greater power of television. That aspect was admirably stressed by Mr. Selwyn Lloyd in his minority report for the Beveridge Committee, and appeared to be the main reason for his disagreement with the majority report and urging the discontinuance of monopoly. Moreover, what was elsewhere urged in the majority report as to the tendency of sound broadcasting and still more of television to encourage passivity is substantiated by the findings of the report by Mr. Silvey already noted. Nor have the debates in Parliament removed this misapprehension, as was shown by the confused analogy with freedom of the press which the Lord Chancellor forced into his speech in concluding for the Government. That the Government has already reconsidered its proposals on the method of appointing governors may warrant the hope that it will think again on the major issues of the regional councils and the introduction of sponsoring. If in response to authoritative and impartial criticism the Government would take the whole question out of the whirlpool of party politics into which its own action has plunged it, a new charter and licence may still come into operation while the debate on monopoly and devolution proceeds. The scientific and technical factors in the development of both sound broadcasting and television should be urgently explored and publicly discussed in order to enable a decision to be taken on whether or not to abandon the existing system of monopoly. Moreover, if the decision were in favour of breaking the monopoly, it could then be done on the basis of a scheme embodying not merely safeguards which would ensure the dominance of the idea of public service and the prevention of the abuse of power, but would also ensure that the fullest possible use was made of the latest scientific and technical advances to give efficient administration and the maximum satisfaction to legitimate regional aspirations.

VAVILOV ON CULTIVATED PLANTS

The Origin, Variation, Immunity and Breeding of Cultivated Plants

Selected Writings of N. I. Vavilov. Translated from the Russian by Dr. K. Starr Chester. (Chronica Botanica, Vol. 13, No. 1–6.) Pp. xviii+364. (Waltham, Mass.: Chronica Botanica Co.; London: Wm. Dawson and Sons, Ltd., 1951.) 7.50 dollars.

NIKOLAI IVANOVITCH VAVILOV was one of the outstanding contributors to the new science of plant breeding which developed during the first half of this century, following on the rediscovery in 1900 of the principles of Mendelian heredity. He was selected by Lenin to administer and direct agricultural research in the Soviet Union, and he became president of the Lenin Academy of Agricultural Sciences, which ultimately came to consist of a chain of four hundred experimental stations, scattered through the U.S.S.R. from Leningrad to Vladivostok.

Vavilov's most important contribution to science was on the genetical significance of the centres of origin of cultivated plants. The theory that cultivated plants can be assigned to known centres of origin was first put forward by de Candolle. Vavilov was able to co-ordinate the vast body of information which had become available since de Candolle, and he also developed the theory that genetical diversity is greatest in these centres of origin. The greatest concentration of dominant genes occurs at the centre of origin, and since many of these have been lost by the more sophisticated varieties of the cultivated regions, it was evident to him that material from these centres can be of the greatest possible use to the plant breeder. His early studies of immunity to disease in plants led him to believe that it is in the centres of origin that immune types are most likely to occur. This now is perhaps over-simplified, since cases are known of recessive immunity away from the centre of origin.

Accordingly, Vavilov organized expeditions to countries where the most important economic plants were thought to have originated. Even before the Russian Revolution, he had explored Persia, Turkmenia and Bokhara. Dobzhansky states that "in 1920–23 he visited various parts of Middle Asia, including Tadjikistan and Pamir. In 1924 he covered a long and arduous itinerary in Afghanistan. In 1925 he went to Khiva. In 1927 he studied the Mediterranean region from Portugal and Morocco to Syria and Trans-Jordan, and made an expedition to Ethiopia and Somaliland. In 1929 he visited Chinese Turkestan and Songaria. Finally, in 1930 and 1932–33 he travelled and collected extensively in Mexico and in central and south America". Altogether, he and his colleagues surveyed sixty different countries.

In this way he was enabled to make a beginning in the great and still unaccomplished task of a survey of world resources of economic plants, and of the formation of a series of living museums in which all the genetical variability of a plant could be made available to workers not only in the U.S.S.R. but also in other countries. His collection of wheat varieties, for example, numbered 26,000 types.

Vavilov was no narrow nationalist. He believed that our main task is to feed, clothe and house the millions of underprivileged human beings who still comprise the bulk of the world's population. For this work, the whole world must be called on to help and serve mankind.

The second important theory of Vavilov is that known as "The Law of Homologous Series in Variation". This puts forward the idea that related species, and even genera, tend to exhibit parallel hereditary variability. This concept has also been of value to the plant breeder, in that it has enabled the existence of useful but unknown variants to be predicted in a given crop.

Although Vavilov's work has long been known and appreciated by non-Russian workers, they have hitherto not been able to read it in complete form. But here in this well-produced and well-translated book are to be found Vavilov's most important writings.

There is an introductory essay on plant breeding as a science. All those that maintain that plant breeding is an art and not a science—an art for which there is a 'flair' possessed by a few—should read and profit by this chapter. Plant breeding is no longer merely an art; it is a branch of biological engineering.

The first section of the book proper covers the subject of the "Phytogeographic Basis of Plant Breeding". All the main centres of origin of cultivated plants, both primary and secondary, are here discussed in detail. Subsequent sections deal with "The Law of Homologous Series in the Inheritance of Variability", and the "Study of Immunity of Plants from Infectious Diseases". The third section is a complete and masterly survey of the "Scientific Bases of Wheat Breeding", and there is a concluding section containing a selected bibliography of the basic world literature on the breeding and genetics of wheat, up to 1935.

A perusal of this classical contribution to biological literature makes it more than ever mysterious why genetical science was destroyed in the Soviet Union at the very time when all the tools were ready to make an unprecedented advance in its practical application to agriculture. The book is a complete defence of plant-breeding technology as we are slowly coming to know it, against the pretensions of the Lysenko school who are now responsible for applied genetics in the Soviet Union. It will be read by all plant breeders; they can scarcely fail to be stimulated by the still novel points of view which abundantly occur. If its lessons are properly appreciated by those who guide our political and economic destinies, we may not attain for a long time to come the twenty thousand workers whom Vavilov had in his research institutes in 1934; but at least we shall hear less of the preposterous story of a possible surplus of biologists in Great Britain during the next five years.

The life and work of Vavilov must be viewed against the background of the political ideology of the Soviet Union, and this book should be read conjointly with the story as told by Huxley and Zirkel of how genetics was destroyed in that country after a long period of hostility. Vavilov died, defeated and disgraced, in Siberia in 1942. It is therefore altogether fitting that his best work should now be made available to the wide audience of the Western world.

S. C. Harland

THE LAW OF PATENTS

Terrell and Shelley on the Law of Patents
Ninth edition. By K. E. Shelley, Q.C. Pp. lxv + 680. (London: Sweet and Maxwell, Ltd., 1951.) 105*s*. net.

"TERRELL on Patents" has been for more than sixty years the standard text-book on the law of patents. This new edition, "Terrell and Shelley on Patents", rendered necessary particularly because of the passing of the recent Patents Act, has been prepared by Mr. K. E. Shelley, one of the most experienced of the small group of Her Majesty's Counsel practising at the Patent Bar. He is to be commended for producing so comprehensive and yet so succinct an account of the law of patents.

The British patent system was subjected to a detailed investigation by the Swan Committee set up in 1944 by the then president of the Board of Trade, under the chairmanship of Sir Kenneth Swan. Important and far-reaching innovations in patent law were recommended by this Committee, and the large majority were incorporated in the Patents Act, 1949.

As Mr. Shelley points out in his preface, patent law falls into two sharply distinguished categories: there is the purely administrative side, which is primarily concerned with the actual procedure of obtaining a patent; and there is the judicial aspect, which is concerned with the interpretation which the courts have placed on general concepts contained in the Patents Acts, such as 'manner of manufacture', 'new', 'useful', etc.

No attempt has been made in this edition to set out every detail of procedure of the administrative branch of the law, though the relevant sections of the Act and the Rules are printed in full in the appendix. The judicial aspect has, however, been very fully treated. Verbatim extracts of the leading judgments on each important topic have been quoted, and the author has not hesitated to criticize many of the decisions of the court. As he points out in his frankly written preface, "It is inevitable that in some cases a Court, approaching a problem of patent law for the first time, has come to a decision which seems erroneous to the specialist who has over a period of years reached a different conclusion, possibly through giving more weight to expediency in practice than to abstract rules of construction or the dictionary meaning of words. Such decisions have been frankly criticized in the following pages". It will be undoubtedly helpful to many a practitioner to have these critical and constructive comments.

In the contents are set out the principal changes enacted by the Patents Act 1949, many of which are likely to make the law more favourable to inventors who patent their inventions. New methods of processing or testing applicable to the improvement or control of manufacture are now patentable. New chemical substances may be patented *per se*, without reference to any particular method of manufacture, and this constitutes a substantial change in the law which is of importance in the chemical industry. Patents of addition are no longer to be invalidated by publication of the main patent or user of the invention which is described in it. Thus an opportunity is now afforded to a patentee to file a fresh application for letters patent covering details of his invention in the light of actual experience. This is likely to avoid the patentee being deprived in future of a chance of obtaining an effective monopoly for his invention.

The book commences with a brief history of the development of patents and the nature of patentable inventions. Next follows a chapter on the applicant and the application, including a valuable résumé of the difficult question which so frequently arises in practice—the extent of the ownership by an employee of an invention conceived while in the employment of a firm. The requirements laid down by the Act as to the contents of the specification and the grounds upon which the specification may be attacked before and after the grant of letters patent are set out in the succeeding chapters. The chapter on the action for infringement, the method by which a patentee in the last resort can enforce his patent privileges, contains an excellent summary of the principal matters to be considered and a review of the more important cases. The sections of the Act dealing with action which can be taken to deal with any abuse of the monopoly granted by way of patents are fully analysed. Now that government departments are so closely connected with industrial research, the sections of the Act dealing with questions of compensation payable by the Crown in respect of use of patented inventions are of considerable practical importance. These questions have been clarified by the new Act and are carefully summarized. No mention, however, is made of the facilities whereby a patentee may in certain circumstances have his claim dealt with by the Royal Commission on Awards to Inventors set up under the chairmanship of Lord Cohen.

While retaining the general layout of the former editions of this standard text-book, this new edition provides a more compact and logical approach to a difficult subject than did its predecessors. The book will be welcomed by all who are in any way concerned with inventions and patents. R. G. LLOYD

A HANDBOOK OF PAPER CHROMATOGRAPHY

Papierchromatographie

Von Dr. Friedrich Cramer. (Monographien zu *Angewandte Chemie* und *Chemie-Ingenieur-Technik*, Nr. 64.) Pp. 81+2 plates. (Weinheim-Bergstr.: Verlag Chemie, G.m.b.H., 1952.) 9.80 D. marks.

Of all forms of chromatography, the paper chromatogram has proved the most popular and is now universally established. Since its inception in 1944, many articles have appeared reviewing its applications; but while these have served a useful purpose, the time has come for something more permanent than a review, and which brings together all the important features and is designed to be a work of reference. This has been accomplished by Dr. F. Cramer in "Papierchromatographie".

The monograph is arranged in two parts, general and special. The first gives the principles underlying the different types of chromatogram. Counter-current distribution is discussed and linked up with partition chromatography. The paper chromatogram is discussed as a partition process, and the arguments against it are also presented. After the theoretical sections, there follows a full and detailed account of the practical aspects of paper chromatography. An outline of the various methods of quantitative analyses is next presented, and then the use of paper, either in sheet or powder form, for isolations. Though not strictly chromatography, paper electrophoresis is usefully included, and this completes the general part.

The special part of the book is concerned with applications to all the important classes—amino-acids, sugars, purines, and so on. The treatment is thorough; many tables of R_F values are given, and full details are provided of solvents, reagents, and some of the more important quantitative methods. Non-aqueous and reversed-phase chromatography and the use of radioactive tracers are not overlooked. The emphasis throughout is on sheet chromatograms; the use of paper and starch in columns is mentioned only briefly.

In a work of this kind, so packed with information, it is perhaps inevitable that errors and omissions occur, but these are remarkably few. The only serious criticism that one can offer is that there is no subject index, which is essential in such a work of reference. Of the few errors, there are one or two references which do not relate to the subject-matter in the text. Of the omissions, there is no reference to Durrum's important contributions on paper electrophoresis[1]. In the section on peptides, which is rather too brief, more could have been said about the techniques for determining the order of amino-acid residues in proteins and polypeptides, and a table of R_F values of peptides and derivatives might have been included. There is no mention of the theories relating R_F values of peptides with the thermodynamics of their structure[2]. A 'map' of the amino-acid spots of a two-dimensional chromatogram would have been useful. Though the illustrations are clear and the colour photographs are good, it is rather a pity that a better two-dimensional chromatogram was not chosen for reproduction.

However, these are small blemishes in a work which provides all the information that one expects from a good text-book. It is up to date, well arranged, generously illustrated and clearly printed on high-quality paper. The price, at present rates of exchange, is reasonable, and it is to be hoped that the book will be generally available outside Germany. Is it too much to ask for the monograph to be supplied in stiff covers? This would, of course, raise the price somewhat, but would be worth while as a protection against inevitable wear and tear. An English translation would undoubtedly widen its appeal. This book will be found invaluable by all, whether experienced or not in the subject, and Dr. Cramer and the publishers are to be congratulated on the production of an attractive text-book of outstanding importance.

R. CONSDEN

ARCHÆOLOGY IN ECUADOR

The Archæology of the Santa Elena Peninsula in South-west Ecuador

By G. H. S. Bushnell. (Occasional Publications of the Cambridge University Museum of Archæology and Ethnology.) Pp. xv+155+5 plates. (Cambridge: At the University Press, 1951.) 42*s*. net.

THIS volume presents the results of Dr. G. H. S. Bushnell's field-work in an area until now practically unknown archæologically, together with a discussion of the small corpus of relevant comparative material, mainly the work of Spanish archæologists.

Dr. Bushnell's excavations indicate the presence on the Santa Elena Peninsula of three separate cultures: Guangala, Engoroy and Manteño. They were nowhere found in stratification, but there is some evidence indicating this sequence. Manteño, previously known from Manabí as probably the last period before the Spanish Conquest, the author considers to be intrusive in the Peninsula. He is rightly cautious about dating, but produces some comparative material suggesting that Guangala, the earliest found, is later than A.D. 900.

Detailed descriptions of these three cultures are given. There is also a brief chapter on a possible pre-Guangala culture (now being further investigated by E. N. Ferdon, jun.), and another on an early post-Conquest cemetery at La Libertad, partly excavated by the author.

Besides much characteristic pottery, sites belonging to all three cultures yielded tools of stone and shell. In Guangala and Manteño sites metal tools and ornaments were found, the single Engoroy site produced no metal. Among Manteño objects were two celts. That these at least were of local manufacture is indicated by the close correspondence of one of them to a clay mould excavated at La Libertad by Mr. A. J. R. Murray in 1923–24 (now in the Pitt Rivers Museum, Oxford). A metallurgical report by the British Non-ferrous Metals Research Association on some of the metal objects (Appendix *A*) shows them to be of copper and not of bronze.

Most of the human remains were either calcined or in very poor condition. In Appendix *B*, Dr. W. L. H. Duckworth reports on the seven skulls of the Guangala period which were capable of preservation. They show artificial deformation at the occiput such as is characteristic of Peruvian skulls, which they resemble in other details also.

In culture, however, Dr. Bushnell thinks that the Guangala period may prove to owe more to Central America than to Peru. For Engoroy he can suggest no outside relationship. He agrees with the view held by Saville from his work at Manabí that the Manteño culture shows "a considerable degree of independence of outside influence".

Although many problems remain unsolved, Dr. Bushnell's work has put into place a piece of the jig-saw puzzle which will eventually be completed to produce a picture of the archæology of coastal Ecuador. The book is well illustrated, with maps and plans, numerous line-drawings, photographs, and an excellent colour plate of Guangala pottery types. It should give a good start to the welcome new series which it inaugurates.

B. M. BLACKWOOD

PHYSIOLOGY OF MITOSIS

The Mitotic Cycle

The Cytoplasm and Nucleus during Interphase and Mitosis. By Dr. Arthur Hughes. Pp. viii+232+16 plates. (London: Butterworths Scientific Publications, Ltd., 1952.) 35*s*. net.

IT is rightly emphasized on the dust-cover of this valuable monograph that the process of cell division presents one of the most difficult problems the experimental biologist has yet attempted to solve, and, if this present account of the mitotic cycle is not an easily flowing and well-balanced narrative, the reflexion is not on the author but on the present state of our knowledge of the subject. There is a large and widely scattered literature of unequal relevance and of uneven quality. The lines of advance have been largely dictated by considerations of the materials and techniques available, and a strong medical bias is also evident. Thus we now have an extensive knowledge of the early cleavage of a certain few eggs, of the growth in culture media of a certain few tissues, of the methods of induction of cancerous growths, and of the methods of mitotic inhibition by a multitude of diverse substances. The obvious questions posed by the mitotic activity of normal animal and plant tissues have been almost entirely neglected, although very recently a start has been made towards their solution.

The book gives an extensive survey of this patchy subject, and it will for many years remain a valuable tool in the hands of those who are working in or around this field of research. Chapters are devoted in turn to the nucleic acids, to the cytoplasm and nucleus in interphase and in division, and to the experimental methods of analysis of the problems presented. Sections are contributed by Dr. M. M. Swann on the spindle, and by Dr. C. Waymouth on the nature of the stimulus to mitosis.

Because this is such an extensive review, the few gaps that are left unfilled appear all the more obvious. In particular, it has to be noted that the short section on hormones and mitosis gives a surprisingly inadequate account of our present fairly extensive knowledge. Another lesser criticism which may also be offered is that the long reference lists are arranged in order of mention and not, as is more customary in biological works, in alphabetical order. This is particularly regrettable, since these lists are one of the most valuable features of the book.

Such criticisms do not, however, invalidate the final judgment that this is certainly the best review of the difficult subject of cell division yet to be published, and its appearance will be warmly welcomed.

W. S. BULLOUGH

Elsevier's Encyclopædia of Organic Chemistry

Edited by F. Radt. Series 3: Carboisocyclic Condensed Compounds. Vol. 14: Supplement; Tetracyclic and Higher-Cyclic Compounds except Steroids and Triterpenes. Pp. xxxi+938S+Ind. 113. (Amsterdam and New York: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1951.) To subscribers, £23.

THIS is the first of the supplementary volumes of "Elsevier's Encyclopædia". It is mainly concerned with the polycyclic aromatic hydrocarbons and their derivatives, and summarizes the literature of the decade 1937–46. There are also references to some of the more important publications of later years, up to and including 1951. The size of this volume bears witness to the large amount of attention which has been devoted to polycyclic aromatic hydrocarbons in recent years; it is pointed out in the preface that the number of ring systems known has undergone a 60 per cent increase, having risen from 233 to 378. The original Vol. 14 consisted of 611 pages, excluding indexes, and included also the steroids and triterpenes which will form the subject of a second part of the supplementary volume.

In general, this supplement follows the pattern of earlier volumes, although a useful novel feature is the inclusion of references to the patent literature. The ring systems dealt with include those of the benzfluorenes and fluoranthene, 1 : 2-benzanthracene and naphthacene, chrysene, pyrene, cholanthrene, pentacene, dibenzanthracenes, picene, benzopyrenes, perylene, and coronene. Recent work on some of the vat dyes is also summarized; these include anthanthrone, pyranthrone, dibenzanthrone and *iso*-dibenzanthrone. There is also reference to some natural products, such as the diterpene phyllocladene and related compounds, and the photodynamic pigment hypericin.

The volume conforms to the customary standard of excellence in production, and will be of particular interest to those who have occasion to consult the literature of carcinogenic hydrocarbons and their derivatives. There are extensive references to their biological properties as well as to preparation and reactions. The volume will also be welcomed by the increasing body of chemists who make regular use of the "Encyclopædia". Unfortunately, only a relatively small area of the field of organic chemistry has been covered by the volumes which have been published so far.

Notions fondamentales sur les vernis et peintures

Par Louis Kientz. Deuxième édition revue et corrigée. Pp. xxi+234. (Paris: Libr. Gauthier-Villars, 1952.) 1300 francs.

M. LOUIS KIENTZ has written this work with the express purpose of providing a modern text-book to which all those who are connected with the different branches of the paint and varnish industry may refer if they wish to learn about recent scientific and technical developments in the industry. He therefore starts by outlining a few basic ideas of chemistry and physics appertaining to paints and varnishes, and discussing the chemistry of the raw materials used, namely, resins, oils, solvents and pigments. He then describes the processes involved in the different stages of the manufacture of various types of paints and varnishes, which are grouped into families under a system of classification introduced during the War by the Comité d'Organization des Peintures et Vernis (C.O.P.V.). There is a final chapter devoted to a survey of methods used for testing both raw materials and the finished paints and varnishes.

The subject-matter dealing with the actual manufacturing processes is clearly and logically presented, but the earlier chapters discussing the purely chemical aspects of the subject are open to a certain amount of criticism. Thus, the drying of oils is discussed without any reference to recent work on the hydroperoxide theory, and the polymerization reactions involved in the formation of stand oil are inadequately treated. It is also misleading, in a modern text-book, to give wood distillation as the only source of acetone. Furthermore, there are a large number of irritating misprints in simple chemical formulæ and equations, and the structural formulæ of compounds such as abietic acid, dipentene and pinene are quite unintelligible and show a complete disregard for the tetravalency of carbon. It is regrettable that these errors occur in what purports to be a revised and corrected edition; they reduce the value of this book, which in other respects may be regarded as a welcome addition to the technical bibliography of the paint and varnish industry.

A. E. A. Werner

A Guide to Bird Finding East of the Mississippi

By Olin Sewall Pettingill, Jr. Pp. xxi+659. (New York and London: Oxford University Press, 1951.) 30*s*. net.

THE title of this book is rather misleading, since it is really a guide-book to the best places to see birds in the twenty-six States east of the Mississippi. The volume is arranged under States, with each locality printed in capital letters, followed by the size in acres, or square miles, in brackets, and a statement whether it is a reserve or park under Federal or State management.

After a brief description of the type of country found in the reserve, some of the more interesting birds are mentioned and directions given how to get to the place. Visitors are warned always to call at the headquarters of a park or reserve before entering, and in the case of a private reserve to make sure of getting the owner's permission. Towns which have museums where there are collections of birds are referred to with a brief description of their contents.

As the author points out, this work was a co-operative undertaking, in the compiling of which three hundred people contributed information. It contains a great deal of interesting information regarding the reserves in the eastern United States, and might well be copied in a modified form in Great Britain.

Dyeing with Coal-Tar Dyestuffs

The Principles Involved and the Methods Employed. By Dr. C. M. Whittaker and C. C. Wilcock. Fifth edition. Pp. vii+375+17 plates. (London: Baillière, Tindall and Cox, 1949.) 21*s*. net.

THOUGH essentially technological, this book makes an approach to a synoptic view of the subject, and should be of value to students of textile chemistry. Theoretical treatment of the subject is notably lacking, however. Thus no adequate attempt is made to show how dyeing-rate depends upon a diffusion process, or how dyeing-rate and dyeing-equilibrium are affected by temperature and by salt addition. In view of the well-known pioneer work of the senior author, these omissions are surprising.

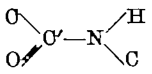
S. M. Neale

STRUCTURE OF PROTEINS

RECENT developments in the study of proteins and synthetic polypeptides have raised hope that some fundamental patterns of protein structure may be elucidated in the not very distant future. Progress in experiment and theory has been revealing to a degree that could scarcely have been anticipated even five years ago. The Royal Society discussion of May 1 on "The Structure of Proteins", organized by Prof. W. T. Astbury, served to focus the attention of many investigators on present achievements and on the deep and baffling problems that still remain to be solved.

The background of the discussion may be briefly sketched. Beginning about twenty years ago, Prof. Astbury and his associates studied the proteins of the keratin–myosin–epidermis–fibrinogen (k–m–e–f) group, all of which show a general similarity in the wide-angle X-ray diffraction pattern, and all of which are capable of existing with the polypeptide chains in a folded (α) or extended (β) configuration. The other great class of fibrous proteins, the collagens, show a fundamentally different type of pattern. The evidence is now overwhelming that protein molecules are composed of polypeptide chains; hence it was sought, by Astbury and others, to formulate configurations for such chains which might explain the observed facts. Thus in 1943 M. L. Huggins proposed a number of possible configurations, some of them helical. In 1950 Sir Lawrence Bragg, J. C. Kendrew and M. F. Perutz examined the problem in great detail, discussing numerous possible patterns of folding of the chains, and for the first time defining the proposed structures with considerable precision by giving the co-ordinates of the atoms to the nearest 0·1 A. However, the results which have aroused the strongest support, and the sharpest criticism, are those of Prof. L. Pauling and Dr. R. B. Corey, whose views were fully presented at the meeting. Fortunately, Dr. Corey was present in person to discuss the dimensions of the polypeptide chain; the involuntary absence of Prof. Pauling was keenly regretted by all at the meeting, and in his absence his paper was presented by Dr. E. W. Hughes.

Dr. Corey's contribution to the discussion rested upon precise studies of the crystal structures of amino-acids and peptides, which he and his associates have carried out over a period of many years. These led to a picture of the most probable dimensions of the amide group, the repeating unit of the polypeptide chain; the results are summarized in the following diagram and table.



Distances	
N—C	1·47 A.
N—C′	1·32 A
C′—O	1·24 A
C′—C	1·53 A.

Bond angles	
C—N—C′	123°
C—N—H	114°
H—N—C′	123°
N—C′—O	125°
N—C′—C	114°
O—C′—C	121°
C′—C—N	110°

Fundamental to all structural considerations is the large amount of double-bond character in the C′—N bond of the amide group, indicated by the short interatomic distance of 1·32 A., contrasted with the normal single-bond value for the C—N linkage, which is near 1·47 A. This implies that all the atoms in this group shown in the formula lie in the same plane, or very nearly so. A twisting of the atom pairs on either side of the C′—N linkage by 10° out of this plane should lead to a strain energy near 1 kcal. per amide group; a 20° twist should produce a strain energy nearly four times as great. Given this planar configuration, the arrangement of the outer carbon atoms may either be *trans*—as shown in the figure—or *cis*. The amide group in all peptides yet studied, and also in N-acetylglycine, has been found to be in the *trans* configuration, and the planarity of the group is maintained to a high degree of approximation.

The paper of Pauling and Corey considered the criteria for acceptable configurations of polypeptide chains in proteins, and laid down certain postulates concerning them. First, interatomic distances and bond angles must be the same, or nearly the same, as those found already in amino-acids and peptides. Secondly, the NH and CO groups must be linked by hydrogen bonds, with reasonable values for the N—H . . . O distance, and with a close approach to linearity of these three atoms. Thirdly, the planarity of the amide group must be maintained. Several configurations which meet these requirements have been formulated; two are helices. The one which appears most important is the α-helix, containing very nearly 3·7 amino-acid residues per turn of the helix, the translation per residue in the direction of the axis of the helix being calculated as 1·49 ± 0·04 A. Precise values for the co-ordinates of the atoms in this helix have been given, and X-ray intensities for scattering from such a structure have been calculated and compared with observed values. The most striking piece of evidence suggesting the existence of the α-helix in proteins was the observation of Perutz of an X-ray reflexion at 1·47–1·50 A., corresponding to a repeating distance along the fibre axis, in all proteins and synthetic polypeptides having the α-configuration. The discovery was made in 1951, following the formulation of the α-helix; it was later recognized that the same reflexion had been observed in certain types of keratin by I. MacArthur in 1943; but its possible implications were not then apparent.

If the helix is to form part of a repeating unit in a crystalline structure, an integral number of residues must be obtained after a reasonable finite number of turns; Pauling has suggested eighteen residues in five turns, or eleven residues in three turns, as probable repeating units within the limits 3·6–3·7 residues per turn. In particular, he proposed an α-helix with eighteen residues in five turns as the basis for the structure of the synthetic substance poly-γ-methyl-L-glutamate, giving a unit length along the fibre axis of 27 A.

Another possible helix, the γ-helix, has about 5·15 residues per turn, and a fibre axis length per residue very near 1 A. This helix has a hole down the centre large enough to admit water molecules; there is at present little evidence, however, to suggest that such a structure exists in Nature, and there are reasons for believing it to be unstable.

Finally, Pauling and Corey have formulated three different kinds of 'pleated sheets'—briefly denoted as the polar, the parallel and the anti-parallel—consisting of sets of peptide chains, more fully extended than in the helices, linked by hydrogen bonds between the chains, rather than within the chain, as in the helix models. The polar pleated sheet they believe to be an improbable structure; the other two, with a length per residue along the chain direction of 3·34 A., are suggested as models for the β-keratin structure.

For collagen they have proposed an elaborate structure, involving three intertwined polypeptide chains, held together by lateral hydrogen bonds. In each chain two *cis* residues are followed by one *trans* residue; every third residue may be proline or hydroxyproline. However, it is now admitted that this structure requires modification.

The principal debate at the meeting centred around the validity of the α-helix. Besides the Perutz–MacArthur spacing at 1·5 A. in many proteins, Pauling cited the recent calculations of W. Cochran and F. H. C. Crick[1] on poly-γ-methyl-L-glutamate in its favour, as well as the radial distribution functions calculated by D. P. Riley and U. W. Arndt[2] for bovine serum albumin from X-ray data on the powdered protein. The latter work was discussed briefly at the meeting by Dr. Riley himself.

On the other hand, some grave difficulties for the α-helix were pointed out. The calculated density of α-keratin, for example, as Astbury pointed out, should be about 1·15 if it is assumed to be composed of α-helices in hexagonal packing. Modification of the packing could give a somewhat higher density, but not nearly enough to explain the observed density near 1·3. The characteristic X-ray spacing at 5·1 A. in α-keratin and other α-proteins should not be given by the α-helix, which instead should give a repeating spacing in the range 5·22–5·62 A. The 5·1-A. reflexion has been interpreted by V. Schomaker (as reported by Pauling) as due to an abnormality in background intensity of poorly crystallized material; but this explanation was obviously not considered satisfactory by some who were present. Moreover, Dr. C. H. Bamford reported new X-ray studies on poly-γ-methyl-L-glutamate, carried out at the Courtauld Laboratories, Maidenhead, which indicate that the repeating unit along the fibre axis is at least 43·2 A., and may be twice as great. If this is correct, it would rule out the view that the fundamental repeat is that of an α-helix with eighteen residues in five turns, as proposed by Pauling. (Attention may be directed at this point to the recent report of Yakel, Pauling and Corey[3] on fibres of the same substance. They find a hexagonal unit cell with $a = 11·58$ A., $c = 26·33$ A., the latter value being in excellent agreement with that expected for an α-helix having eighteen residues in five turns. Moreover, the intensities of the X-ray reflexions agree extremely well with those calculated for the α-helix, the β-carbon atoms being assigned to position 2, in the notation of Pauling and Corey. This evidence, together with the striking calculations of Cochran and Crick[1], strongly supports the view that poly-γ-methyl-L-glutamate fibres have the α-helix structure, or something very close to it (see also Bamford *et al.*[4]). It would require only a very small distortion of the helix to give a large change in the repeat distance along the fibre axis, and such distortions may well occur in certain cases, depending on the method of preparing and drawing the fibre. Further work is certainly needed to resolve the puzzle completely; but the balance of the evidence on these synthetic polypeptides seems to be in favour of the α-helix.) Dr. Bamford favours a structure for α-proteins in which there are only two amino-acid residues for a repeating distance of 5·1 A. along the fibre axis, instead of three, as in the Pauling–Corey α-helix or in another structure proposed earlier by Astbury. However, this hypothesis has serious difficulties also, which some consider to be fatal.

One of these difficulties was brought out in the report by Dr. K. M. Rudall on the elastic properties of myosin, epidermin and fibrin. Films and fibres of these proteins were stretched under conditions in which they were fully converted into the β form, and then caused to shorten into the α form. The maximum contraction in all cases seems to be about 55 per cent of the stretched length. This figure corresponds closely with what would be expected on the Pauling–Corey hypothesis—contraction from a pleated sheet with 3·34 A. per residue to an α-helix with 1·50 A. per residue—but could also fit the Astbury model for α-keratin. It seems irreconcilable with a model involving only two residues in a fibre axis distance of 5·1 A., unless the α–β transformation is supposed to be far less complete than it appears.

The Pauling–Corey collagen structure—which the authors themselves now state requires revision—was criticized by Prof. J. T. Randall, who objected to the mixture of *cis* and *trans* residues involved, and to the failure of the structure to explain the infra-red dichroism. Prof. Randall proposed an alternative structure, which appears to avoid these difficulties, and which he believes to give a better fit with the X-ray data (see *Nature*, June 21, p. 1029).

Work of Dr. Barbara W. Low at Harvard University (reported to the meeting by J. T. Edsall) on crystals of acid insulin sulphate, indicating the presence of oriented polypeptide chains, has recently been published[5]. Dr. Low also reported a new type of helical model, intermediate between the α- and the γ-helix; each amide group is hydrogen-bonded to the fourth one beyond it, and the distance per residue along the fibre axis is about 1·13 A. This model requires slight distortion of the bond angle of the α-carbon; calculations on the model are still in a preliminary stage. Dr. Dorothy Crowfoot Hodgkin presented Fourier projections of the phenylalanyl (*B*) chain of insulin, using the sequence of amino-acid residues determined by F. Sanger, and assuming the chain to be coiled in an α-helix.

A. Elliott discussed the infra-red absorption and dichroism of synthetic polypeptides in the α and β forms. The parallel dichroism in oriented specimens of poly-γ-benzyl-L-glutamate shows that the C=O and N—H bonds are directed along the chain axis rather than across it, and that the chains are folded. However, the dichroic ratio of the C=O frequency is much less than that of the N—H frequency. The significance of this finding for bond angles and distances in the structure was considered at length; one important point, brought out by W. C. Price, is that the dipole moment change in the C=O vibration may involve also the adjoining C—N linkage, on account of resonance in the amide group and of the 'orbital-following' effect. Hence, the infra-red dichroism may not give a correct indication of the orientation of the C=O bond. Studies on simple substances of known structure are needed; Elliott and his associates are now studying acetanilide, the crystal structure of which is partly but not yet fully known.

Sir Lawrence Bragg and Dr. Perutz presented their latest work on the structure of hæmoglobin; the study involves an attempt to determine a complete Fourier projection of the hæmoglobin molecule from a study of the *h0l* reflexions, using all the data obtainable by varying the water and salt content of the crystals, and the chemical nature and species of the hæmoglobin. The pattern of the molecule should be resolvable within about 7 A. when the signs of all terms have been determined. Dr. C. H. Carlisle and Prof. J. D. Bernal discussed the crystal structure of ribonuclease. Dr. Carlisle discussed Patterson projections, inferring that parallel polypeptide chains appear to be present in the structure, but that these do not have the right packing and cross-section for α-helices. Prof. Bernal attacked the problem by a very different approach, selecting constellations of 'significant reflexions' as the starting-point for Fourier computations; the method does not lend itself to brief exposition and can only be mentioned here [see *Nature*, June 14, p. 1007].

Dr. K. Bailey reported his work[4] on the size and shape of the very asymmetric molecule, tropomyosin, which appears to be about 385 A. long, with an axial ratio about 22 : 1, and a molecular weight of 53,000. It contains no free α-amino group, and one free α-carboxyl. It is composed probably of two more-or-less parallel polypeptide chains.

H. E. Huxley reported low-angle X-ray studies on living muscle, which reveal the presence of very long molecules, packed in hexagonal array, and 450 A. apart. The relative intensities of the first- and second-order transverse reflexions from this spacing are completely reversed by removing adenosine triphosphate from the muscle. Along the fibre axis there is a repeating unit 420 A. in length; this seems to be due to the actin component, rather than to the myosin. Surprisingly, this spacing does not change on stretching the muscle. The axial and transverse patterns are still clearly observed in glycerol-extracted fibres (Szent-Györgyi's technique). This opens the possibility of studying contracted fibres by X-ray methods.

Although many topics were discussed at the meeting, the prime emphasis was on the underlying structural pattern of the polypeptide chains in proteins. As Dr. Corey remarked near the end, structures such as those proposed by Pauling are precisely defined; they lead to definite predictions about physical properties, and critics can attack these structures where they fail to fit the facts. Revised and improved models can then be put forward, and progress in this supremely important field should proceed with increasing rapidity.

JOHN T. EDSALL

KODAIKANAL OBSERVATORY

By DR. A. K. DAS

Director, Kodaikanal Observatory

THE Kodaikanal Observatory completed fifty years of astrophysical work in March 1951. The occasion was celebrated by a simple function held on September 18 over which His Highness Maharajah Sir Krishnakumarsinghji Bhavsinghji of Bhavnagar, Governor of Madras, presided, and a souvenir pamphlet describing the activities of the Observatory during the half-century was issued to commemorate the occasion.

Kodaikanal Observatory has its roots in the fairly distant past, for it is really the continuation of the Madras Observatory which was started in 1792 by the East India Company "for promoting the knowledge of astronomy, geography and navigation in India". Mr. N. R. Pogson, who was in charge of the Madras Observatory during 1861–91 and whose work in positional astronomy is well known, was the first astronomer to conceive the idea of establishing a branch of the Madras Observatory in the Palni or the Nilgiri Hills especially for photographic and spectroscopic observations of the sun and the stars. But it was in the time of Mr. Charles Michie Smith that the idea took practical shape, and a site at Kodaikanal (elevation 7,688 ft. above mean sea-level) in the Palni Hills was chosen for this branch. The foundation stone of the new Observatory at Kodaikanal was laid in 1895, and by 1901, when systematic solar observations were begun at Kodaikanal, the astronomical work of the Madras Observatory had almost completely ceased and practically all its equipment, except the historical meridian circle, had been transferred to Kodaikanal. However, the astronomical observatory at Madras still existed, though only in name; and Mr. Michie Smith's official designation was "Director of Kodaikanal and Madras Observatories", a designation which continued until 1932, when Kodaikanal Observatory's connexion with Madras came to an end.

Mr. John Evershed, who succeeded Mr. Michie Smith as director, joined the Kodaikanal Observatory in 1907 as assistant director. In 1909 he discovered the phenomenon of radial motion in sunspots which is commonly known as the Evershed effect. When Mr. Evershed became director in 1911, Dr. Thomas Royds joined as assistant director, and their fruitful collaboration continued until Mr. Evershed's retirement in 1922. A very considerable part of the accurate spectroscopic work for which this Observatory is noted was done during the period 1907–22. The tradition of high-dispersion spectroscopic work built up during this period has continued until the present day. But Dr. Royds, during his directorship, which lasted from 1922 until 1937, placed a good deal of emphasis also on the observational study of solar prominences and dark markings. Dr. A. L. Narayan, who was assistant director during 1928–37, succeeded Dr. Royds as director and remained in charge of the Observatory until about the middle of 1946. He was responsible for a considerable amount of work in atomic and molecular spectroscopy. Dr. A. K. Das, who as assistant director between 1937 and 1942 made theoretical studies of the motion of gases in the sun's atmosphere, returned to the Observatory after the Second World War and succeeded Dr. Narayan as director. Dr. R. Ananthakrishnan joined the Observatory as assistant director towards the end of 1946.

Since 1946 the spectroscopic equipment of the Observatory has been greatly improved by the construction of a number of high-dispersion spectrographs, siderostats, cœlostats, etc., and work on various problems of solar physics is in progress. It is expected that a 100-ft. solar spectrograph, a polarizing monochromator and a Lyot coronagraph will shortly be added to the equipment of the solar physics section. The most notable post-war developments in the activities of the Observatory have been, however, the addition of a magnetic and ionospheric branch and

of a section of stellar physics. The magnetic observatory, which was started towards the end of 1949, is now in full operation and is equipped with a set of Watson magnetographs, a set of La Cour magnetographs and the usual accessories; the equipment of the magnetic observatory will shortly be further strengthened by the addition of an Askania magnetic field balance, as well as a set of *QHM* and *BMZ* instruments. The principal instrument of the ionospheric observatory, which started functioning from the beginning of 1952, is an automatic multifrequency ionosphere recorder of the latest type designed by the U.S. Bureau of Standards. The magnetic and ionospheric section naturally has an electronics laboratory attached to it. Recently an equipment for the study of solar radio radiation in the 100 Mc./s. region has been built in the electronics laboratory and has been brought into regular use. Mr. B. N. Bhargava, who had his specialized training in radio-physics in the United States, is in charge of the magnetic and ionospheric section. The stellar physics section has made a modest beginning with a 20-in. Cassegrain reflector by Grubb as its principal instrument. Though old, it is an excellent and very versatile telescope which originally belonged to the now disused Observatory of Poona called after His Highness Maharajah Takhtasinghji of Bhavnagar. This telescope was presented to the Kodaikanal Observatory many years ago, but had remained unused and dismantled. Recently it has been installed for regular use after reconstructing several of its missing or damaged parts, and has been named the Bhavnagar telescope. Work on planetary spectra and some aspects of stellar spectroscopy is being begun with this instrument. Our plans for the development of the stellar physics section include the acquisition of a large Schmidt–Cassegrain telescope and a large reflector of about 100-in. aperture as soon as the necessary funds become available.

The developments that have already taken place have necessitated considerable improvements in our workshop facilities. The Observatory machine shop is now equipped for meeting most requirements of a modern astrophysical observatory; an optical workshop for the Observatory is also one of our projects.

PASTURE AND FODDER DEVELOPMENT IN MEDITERRANEAN COUNTRIES

THERE are a number of countries in the south of Europe and the north of Africa which have sufficient in common to be grouped as the Mediterranean area but in which there is also diversity of topography and, to some extent, of climate: the rainfall varies from 200 to 1,000 mm. a year. The prevalence of limestone rock with soils derived therefrom is a characteristic of this area; but there are considerable areas of igneous rocks, although here, too, practically all the overlying soils are directly related to these rocks. The olive and the evergreen oak are characteristics of the area; indeed, it may be said that a map of the olive and evergreen oak is a map of the typical Mediterranean area. The past history of these countries—invasions, wars and tribal movements—have necessarily affected the people's way of life and the agricultural traditions that have come to be established, but the influence of the past is not now easy to diagnose in its entirety.

There are some specialized crops, particularly the vine and the olive, that are long established and the management of which is generally good; but the cultivation of the more utilitarian crops is mostly unsatisfactory, and arable work on a rotational basis is very weak. Wheat is a dominant crop, and an alternation of wheat and fallow is the chief rotation.

Except in some parts of the south of France, there is a very great deal of pressure on the land to secure the livelihood of the people, and this arises to a considerable extent from the deterioration that has put some areas completely out of cultivation. There has in the past been a good deal of forest destruction, not only to make room for arable cultivation but also to provide wood for buildings and for ships; in consequence, there has been considerable denudation and erosion, and over-grazing has intensified this decline.

The keeping of small animals, particularly sheep and goats, is very common. The keeping of one or two animals by a family is quite normal, but there are also professional shepherds with their flocks. None of the stock, however, is developed for one primary purpose; almost every animal is a multiple-purpose animal to produce whatever labour, milk, meat, skin and so forth it can.

In addition to the defects in crop husbandry itself is the lack of integration between crop and animal husbandry. There is very little pasture specifically cultivated for grazing. Grazing is largely a random affair, and the stock graze in areas that are inaccessible for ploughing or on crop residues. The shepherds who keep flocks of sheep have little grazing ground which is their own, and these shepherds make financial arrangements wherever they can for their flocks to graze.

The Mediterranean farmer has for a long time followed tradition without receiving much inspiration for the development of new ideas, but it does seem that these people are amenable to help and guidance in raising the level of their farming. The pasture and forage problems are crucial to the progress that can be made, and in this connexion the Organization for European Economic Development has produced a report, entitled "Pasture and Fodder Development in Mediterranean Countries"*, which should be the means of big developments and considerable transformation. For some time now the Food and Agricultural Committee of the Organization has been concerned with the development of grassland in Europe, and, following a conference in Paris during May 1950, it published "Farm Advisory Methods for Grassland Improvement". It was during the Paris conference that the need for studying pasture and fodder production in the Mediterranean area was stressed and, in preparation for a conference on the matter, the countries concerned were surveyed by a number of experts from the United States, Australia, South Africa and Great Britain. Each of these experts worked with suitable colleagues in the country concerned, and reports on the various countries are published in Part 2 of the present publication of the Organization for European Economic Development. The reports were discussed first with representatives of the various countries and then at a conference in Rome in June 1951, when a number of important recommendations were agreed.

---

* Pasture and Fodder Development in Mediterranean Countries. (Technical Assistance Mission No. 58.) Pp. 176. (Paris: Organization for European Economic Co-operation; London: H.M. Stationery Office, 1951.) n.p.

A fundamental consideration in pasture and forage development is necessarily the climate and its effect on the growing season. Information about climatic conditions is essential if experience in one area is to be helpful in another, and if the introduction of plants from one region to another is to be carried out rationally. It was therefore recommended in the report that studies of climate and the keeping of reliable meteorological records must be undertaken, and suggestions for the minimum necessary undertakings are made.

A few of the indigenous plants in these countries have been developed commercially; but for the most part they have not been systematically studied and assessed, although this is work that provides essential data for pasture improvement and, as the report points out, can be effective in a very short time. The conference also urged that each country should, in due course, introduce and test species and strains from other countries, and that a systematic programme of seed production should be made possible.

Following systematic study in a country of plants involved in pastures, the integration of pastures and fodder for grazing with its whole scheme of arable farming must be studied and developed. It is suggested that a first step in this matter might be the incorporation of an annual fodder crop into the familiar cereal/fallow rotation, and that, where the climate permits, the fallow be replaced by an appropriate legume, so that in due course this might be developed into a wheat/legume/legume rotation, with wheat every third year, or, in the drier parts, the rotation might be wheat/legume/fallow. The lengthening of rotations in this way should, where it is possible, bring in grazing animals. This will admittedly be difficult in some areas of small holdings where there is no communal grazing, but it is a programme to be aimed at. Moreover, at the present time animal production is very much affected by seasonal food production, and an appropriate development of the continuous production of fodder all the year round is a vital matter.

There are many other lines of work suggested for the improvement of pasture and forage; but the conference has not been unmindful of important economic aspects. Improvements in production will be justified only when and where there are appropriate markets, and in some cases potential markets will need development. The need for increasing the consumption of milk in these countries is one important matter in this connexion. Better farm implements are required; and it is realized, too, that there must be a development in the use of fertilizers (at present much of the land is very poor, particularly in phosphate and nitrogen), and a definite price policy in the development of fertilizers will be required. The need for credit facilities also received the attention of the conference.

The conference expressed the hope that the interest of pasture and fodder developments in the Mediterranean countries will justify the establishment of research stations and pilot farms, and also of a journal and a Mediterranean grassland committee.

A number of technical papers bearing on the subject of the conference were read at the Rome meeting and are produced in Part 3 of the report.

N. M. Comber

NEWS and VIEWS

Directorship of the Lister Institute:

Sir Alan Drury, C.B.E., F.R.S.

The retirement is announced of Sir Alan Drury from the directorship of the Lister Institute, London, which he has held since 1943. Sir Alan assumed the directorship at a difficult period in the history of the Institute, the work of which had been much disorganized by the War. He brought to his task not only his outstanding personal qualities of patience and quiet efficiency, but also a wide knowledge of many aspects of medical research which he had acquired through long service on the scientific staff of the Medical Research Council. His experience included clinical research with the late Sir Thomas Lewis, many years of distinguished work in experimental pathology at Cambridge and a period of most valuable service during the War in the Council's headquarters office. Under Sir Alan's guidance, the Lister Institute has been restored to its position as a centre of active medical research, sustaining its earlier reputation for work in immunochemistry and becoming well known for investigations of blood groups and blood products; it has also taken on new and important responsibilities in connexion with the preparation of sera and vaccines. During his directorship Sir Alan has served as a member of the Medical and the Agricultural Research Council, and both bodies owe much to his help and advice. It is inevitable that the many administrative burdens which Sir Alan has had to shoulder should have greatly restricted his opportunities for personal research at the Lister Institute. It is good, therefore, to know that after his retirement such opportunities will be restored to him when he takes up his work in the Agricultural Research Council's Institute of Animal Physiology. Sir Alan's personal qualities and scientific attainments ensure that the research in experimental pathology which is to be under his care in this Institute will develop on sound lines.

Dr. A. A. Miles

Dr. A. A. Miles, who is to succeed Sir Alan Drury as director of the Lister Institute, has been, since 1946, director of the Division of Biological Standards at the National Institute for Medical Research; for the past five years he has also been deputy director of the Institute. Before his appointment to the scientific staff of the Medical Research Council, Dr. Miles had become recognized as one of the leading bacteriologists in Great Britain. He had had fruitful periods of work at the London School of Hygiene, at Cambridge, at the Postgraduate Medical School in London, and as professor of bacteriology at University College Hospital Medical School, London, where he showed himself to be an outstandingly successful teacher. During his tenure of the latter appointment he had, throughout the War, the responsible position of sector pathologist within the Emergency Medical Service. As director of the Division of Biological Standards at the National Institute for Medical Research, Dr. Miles has had the task of continuing and developing the work so admirably built up by Sir Percival Hartley. The international appreciation which his efforts have met with is shown by his election as chairman of the Expert Committee on Biological Standardization of the World Health Organization. Dr. Miles has not allowed his official duties to diminish his enthusiasm for investigation. He has been throughout, and he continues to be, an active research worker, being best known for his immunological studies of *Brucella* and, more recently, for his investigation of factors affecting the spread of infection within the animal body. In him the Lister Institute acquires a director of wide knowledge and experience, under whose energetic leadership research work will have every encouragement.

Bacteriology in Leeds:

Prof. J. W. McLeod, O.B.E., F.R.S.

James Walter McLeod, who is retiring from the Brotherton chair of bacteriology in the University of Leeds, has profoundly influenced the development of his subject during the past thirty years. Born in January 1887, he received his early education at George Watson's College, Edinburgh, in Lausanne, and at Mill Hill School, and entered the University of Glasgow in 1903, graduating M.B., Ch.B. in 1908. He showed early that his interests lay in laboratory medicine, and, after a year of clinical training in the wards of John Cowan and Sir Kennedy Dalziel, he commenced research in bacteriology with Sir Robert Muir, and was appointed lecturer in pathology at Charing Cross Hospital, London, in 1909; during the First World War he served with distinction—mentioned in dispatches four times and awarded the O.B.E.—in the R.A.M.C. as officer commanding a mobile laboratory. On demobilization McLeod was appointed lecturer in bacteriology at the University of Leeds and became the first incumbent of the Brotherton chair in 1922. During thirty years his contributions to the subject of bacteriology have been notable for their quality and diversity: the pathogenicity of streptococci, the problems of bacterial nutrition and respiration, study of the anaerobes, of the gonococcus, of diphtheria (both as a problem of bacteriology and of epidemiology), have among many other subjects claimed his attention, and in no instance have his findings failed to stand the test of time. Combining the outlook of a general biologist with the exactitude of a physicist and the humanity of a physician, it was but natural that the most notable influence which his work has exerted has been to integrate the study of bacteriology as a subject *per se* with its application to medicine. The honours which he has so rightly deserved—fellowship of the Royal Society, honorary D.Sc. of the University of Dublin, presidency of the Society of General Microbiology—have been a source of very real pleasure to all who know him, and his friends wish him every happiness in his retirement.

Dr. C. L. Oakley

Dr. Cyril Leslie Oakley, who succeeds Prof. McLeod, was born in 1907 and graduated in medicine from University College, London, in 1930, taking a first-class honours B.Sc. in zoology at the same time; three years later he took his M.D. in pathology. After three years as Graham Scholar at the University College Hospital Medical School, he was appointed experimental pathologist at the Wellcome Research Laboratories, Beckenham, in 1934, becoming head of the Immunology and Experimental Pathology Department in 1947. He was elected a Fellow of University College, London, in 1950. During the Second World War he was responsible for the organization of a subsidiary unit of the Laboratories, at Carshalton, where part of the very large production of antitoxin and prophylactics for the Army was carried on. While a Graham Scholar, Dr. Oakley worked on the rate of regeneration of red cells after repeated bleedings. In his first years at Beckenham, besides being responsible for all the morbid histology work of the Laboratories, he worked on virus diseases, particularly influenza, setting up his own unit for making Elford membranes. He then became interested in the pathogenic *Clostridia* and, with his collaborator, Dr. G. H. Warrack, added greatly to the knowledge of the complex antigenic constitution of this group, discovering a number of new toxins and enzymes. He has of recent years, by the use of an ingenious method of immunization with two toxoids simultaneously, furthered very considerably our knowledge of the site of origin of antitoxin. One of the most remarkable observations in this work was the demonstration that aluminium hydroxide adsorbs tetanus or diphtheria toxoid when injected into omental or perirenal fat, and leads to a local production of antitoxin. Dr. Oakley has never abandoned his early zoological interest, and one of his hobbies has been a serious research into the anatomy and systematics of parasitic copepods.

University of Aberdeen

The honorary degree of LL.D. of the University of Aberdeen has been conferred on the following, among others: Prof. Niels Bohr, professor of theoretical physics, University of Copenhagen; Prof. H. Butterfield, professor of modern history in the University of Cambridge since 1944; Prof. James Ritchie, professor of natural history in the University of Edinburgh since 1936; Prof. H. E. Shortt, professor of medical protozoology in the University of London and head of the Department of Parasitology in the London School of Hygiene and Tropical Medicine; and Prof. David Landsborough Thomson, professor of biochemistry in McGill University, Montreal, since 1937.

Medicine and the Mind

For his Rede Lecture, given to the University of Cambridge this year and now published (pp. 30; Cambridge: At the University Press, 1952; 2*s*. 6*d*. net), Sir Russell Brain, president of the Royal College of Physicians, chose as his subject "The Contribution of Medicine to Our Idea of the Mind". Sir Russell pointed out that from an early stage of his training the medical practitioner is made aware of the intimate relationship between the body and the mind, that is, he is always dealing with a body–mind unity, though his chief concern may be with one or the other. The great advances in neurophysiology, neurology and psychiatry during the present century have given us a much more detailed knowledge, enabling us to correlate brain disturbance with mental changes. Disease has made a great contribution to our knowledge of the normal brain–mind relationship, and research has been facilitated by the use of the electro-encephalograph, a machine for amplifying and recording the minute electrical brain-rhythms. It is now known that certain people who behave abnormally have abnormal brain rhythms. Independently of the work of the neuro-physiologists and neuro-psychiatrists, a school of psychological thought has developed which seeks to give a psychological explanation of many forms of mental abnormality, and again the abnormal has thrown light on the normal. The pioneer work of Freud in this field, continued Sir Russell, has been as revolutionary in the interpretation of the mind as was the work of Darwin in the interpretation of the body. Freud did not discover the unconscious mind, for many thinkers deduced it from a study of human thought and behaviour; but he developed the idea practically and produced evidence to show that experiences involving strong emotions might continue to influence behaviour though they had been forgotten, and that feelings such as anxiety might persist divorced from the original ideas. Certain philosophical questions are involved; for example, why is consciousness necessary at all, and why is it associated with some functions of the brain and not with others? The recent contribution of medicine to our ideas of the mind have been, like most of modern science, analytical. But, as Sir Russell emphasized, medicine is also an art, and as an art must realize that the whole man is more than the sum total of parts. It is necessary, more than ever, to find a way of harmonizing logic, philosophy and humanity.

FAO MEMO: New Leaflet of the United Nations Food and Agriculture Organization

THE accounts of the activities of the Food and Agriculture Organization of the United Nations, available as yearbooks and other official publications, are often beyond the scope of the non-technical reader, who nevertheless is interested in the practical steps being taken to overcome hunger and raise the standard of living in various parts of the world. To meet the need of this section of the public, the Organization has started a new illustrated leaflet, *FAO MEMO*, which gives, in semi-popular form, short authentic accounts of its very varied work. In the first issue, which appeared in March, one learns of the success of the publicity campaign in Santiago for encouraging the production and consumption of fish, and in the following number of the project for turning the Jizan region of Saudi Arabia, liable to disastrous extremes of drought and flood, into a flourishing agricultural district by controlling the water supply. Accounts are also given of the useful work being done in the development of rural community life in the Pátzcuaro Lake region of Mexico, and of some occasions, notably that of the recent hurricane in Jamaica, when valuable technical assistance was provided. The *MEMO* is published monthly by the Informational and Educational Services in Rome of the Food and Agriculture Organization, and by the Regional Information Offices in Bangkok, Cairo, New Delhi, Mexico City, and Washington, D.C. Copies of the European edition can be obtained from the Documents Service, Food and Agriculture Organization, Viale delle Terme di Caracalla, Rome, and of the other editions from the appropriate regional offices.

Food and Agriculture Organization: David Lubin Memorial Library

AT a formal ceremony on June 10 the library of the Food and Agriculture Organization of the United Nations was inaugurated in Rome by the director-general, Norris E. Dodd, in the presence of the Council of the Organization, the American Ambassador to Italy, the Italian Minister of Agriculture and representatives of members of the Food and Agriculture Organization. The children and the secretary of David Lubin, founder of the Institut International de l'Agriculture and of its library of some 350,000 publications, which now forms the most substantial and important part of the Food and Agriculture Organization's library of some 400,000 works were among the guests at the opening ceremony. Housed in the modern building generously made available by the Italian Government, the library contains reading rooms, reference, photostat, microfilm services and eighteen kilometres of shelves. In opening it to the public, Mr. Dodd said, "It is a living resource for the service of the world's agriculture. We wish to make it as open as possible to all scholars and technicians and research workers".

Scientific and Technical Periodicals Published in East Asia

THE East Asia Science Co-operation Office, Manila, has issued a list, compiled in 1950, of scientific and technical periodicals published in South-East Asia. The periodicals are listed separately under the Philippines, Indonesia, Malaya, Thailand, Indo-China and Hong Kong, but for each country they are arranged in fourteen broad categories and are also entered in an index by categories covering all six countries. The list covers 142 periodicals and includes particulars of publishers and rates of subscriptions. There is, in addition, an alphabetical index to periodicals arranged under countries. The Office has also issued a supplement to the list, which gives details of some 119 Chinese periodicals. This was compiled in the Shanghai bureau of the Office at the end of 1950 and was revised in the summer of 1951. The supplement is considered incomplete, especially for periodicals published outside Shanghai. Titles are listed alphabetically and also classified by subjects, and particulars of publishers, language, frequency, subscription and commencement of publication are included. The co-operation of scientific workers and librarians in repairing omissions and correcting errors in the list as a whole is invited.

British Thomson-Houston Engineering Research Fellowships

THE British Thomson-Houston Co., Ltd., has instituted the award (annually) of engineering research fellowships. The award is open to honours graduates who are in their last year of apprenticeship with the Company. The holder of a fellowship will engage in engineering research for a limited period (one to three years) either wholly within the Company or partly within the Company and partly at a university. He will work under the supervision of a senior engineer of the Company and under the guidance of a Research Fellowship Panel set up for the purpose. The Director of Research and Education is chairman of the Panel, which includes other senior executives of the Company and, in addition, Prof. E. B. Moullin and Prof. Willis Jackson. This year (1952) fellowships have been awarded to P. H. G. Allen and P. C. McNeill. Mr. Allen was educated at King Edward VI Grammar School, and the City College, Norwich. During the War he served with the Royal Engineers and was a prisoner-of-war in Japan for three and a half years. On demobilization, he studied at King's College, London, and obtained his degree in electrical engineering with first-class honours in 1950. His research will be concerned with heat flow in large transformers. Mr. McNeill was educated at Loretto School, Midlothian. During the

War he served with R.E.M.E. and was demobilized in 1947 with the rank of captain. He then studied at Queen's University, Belfast, and graduated with first-class honours both in electrical and in mechanical engineering in 1950. His research will be on the secondary emission coefficients in magnetrons.

Ramsay Memorial Fellowships

THE Ramsay Memorial Fellowships Trustees have made the following awards of new fellowships in chemistry for 1952–53: Mr. D. Clark, a British Fellowship of £500 a year at the University of Birmingham; Mr. R. F. Webb, a British Fellowship of £500 a year at the University of Cambridge; Dr. G. S. Trick, a Canadian Fellowship at King's College, London; Mr. Juan Llopis Mari, a Spanish Fellowship at King's College, London; Mr. R. O. Steiner, a Swiss Fellowship at the Imperial College of Science and Technology, London; Mr. David R. Lide, a United States Fellowship at the University of Oxford. The Trustees have renewed the following fellowships for the same year: Mr. L. E. Lyons (British Fellowship) at University College, London; Mr. James Jack (Glasgow Fellowship) at the University of Cambridge; Dr. Serafin Novoa (Spanish Fellowship) at the University of Oxford.

Botanical Society of Bengal: Annual General Meeting and Officers

THE annual general meeting of the Botanical Society of Bengal was held on April 27 at the Botany Laboratory, Presidency College, Calcutta. Dr. J. C. Sen Gupta, principal of the College, who is also the president of the Society, pointed out in his address that the physiology of plants with which we are at present familiar is a physiology of the plants of the temperate climate of Europe and North America, and he stressed the importance of a thorough research on the physiology of tropical plants. This will also help in future plans for research on improvement of agricultural crops, medicinal plants and other plants of economic importance. He also laid stress on the need for enlarging the scope of study in plant physiology at Indian universities and pointed out the great importance of taking necessary steps for the establishment of an institute of plant physiology in or near Calcutta. The chief guest at the meeting, H.E. Dr. H. C. Mookerjee, spoke on the need of research for the betterment of crop yields and the introduction and synthesis of new fruits, etc.; he also emphasized that there should be more members of the Society, and all of them should undertake co-ordinated research. The following officers of the Society were elected: *President*, Dr. J. C. Sen Gupta; *Vice-Presidents*, Dr. K. P. Biswas and Prof. P. C. Sarbadhikari; *Secretary for Foreign Correspondence*, Sri A. K. Ghosh; *Councillors*, Dr. H. K. Nandi, Dr. S. M. Sircar, Dr. P. N. Bhaduri, Dr. H. L. Chakravorty, Dr. B. K. Kar, Prof. B. K. Mitra and Dr. P. N. Nandi; *Editor of Publications*, Prof. S. R. Bose; *Honorary Secretary*, Dr. N. K. Sen (35 Ballygunge Road, Calcutta 19); *Honorary Treasurer*, Sri P. K. Bose; and *Honorary Librarian*, J. Sen.

Symposium on Combustion

AN international symposium on combustion is to be held at the Massachusetts Institute of Technology during September 1–5. It is expected that about a hundred papers will be presented, from Great Britain, France, Holland, Belgium, Germany, Japan and the United States. Emphasis is being placed on the physical aspects of combustion, particularly wave phenomena and turbulence, treated from both the experimental and theoretical points of view. The complete papers will appear later in a single volume, like that issued after a similar symposium held in 1948. Further information can be obtained from the Summer Session Office, Combustion Symposium Committee, Massachusetts Institute of Technology, Cambridge 39, Massachusetts, or from Prof. Hoyt C. Hottel, professor of fuel engineering at the Institute, who is co-chairman of the symposium.

Forthcoming Congresses associated with International Scientific Unions

THE following meetings associated with international scientific unions are taking place in the next few months: the Royal Society, through its British national committees, is the adhering body for Britain to each of the unions, and available information of these congresses may be obtained from the Assistant Secretary of the Royal Society (Burlington House, Piccadilly, London, W.1). *Astronomy:* Eighth General Assembly of the International Astronomical Union (Rome, September 4–13); *Geography:* Eighth General Assembly of the International Geographical Union (Washington, August 8–15, to coincide with the seventeenth International Geographical Congress); *Theoretical and Applied Mechanics:* Third General Assembly of the International Union of Theoretical and Applied Mechanics (Istanbul, August 20–28, to coincide with the seventh International Congress of Applied Mechanics); *Scientific Radio:* Tenth General Assembly of the International Union of Scientific Radio (Sydney, August 11–23); *Analytical Chemistry:* First International Congress on Analytical Chemistry (Oxford, September 4–9); meetings of the Analytical Chemistry Section of the International Union of Pure and Applied Chemistry will take place during the period of the Congress; *International Council of Scientific Unions:* Sixth General Assembly of the International Council of Scientific Unions (Amsterdam, October 1–3).

University of London

DR. F. L. WARREN, reader in biochemistry in University College, has been appointed to the University chair of biochemistry tenable at London Hospital Medical College. Dr. Eric Neil, senior lecturer in physiology in Middlesex Hospital Medical School, has been appointed to the University readership in physiology tenable at Middlesex Hospital Medical School. Dr. W. S. Bullough, honorary lecturer in the University of Sheffield, has been appointed to the University chair of zoology tenable at Birkbeck College.

Colonial Service: Recent Appointments

THE following appointments have recently been made in the Colonial Service: R. B. Allnutt (director of agriculture, Leeward Islands), assistant director of agriculture, Nigeria; R. Aribisala, J. A. Carter, R. F. S. Hainsworth, D. R. E. Jackson, J. O. I. Longe, R. Miller and P. Mulholland (agricultural superintendents, Nigeria), agricultural officers, Nigeria; E. J. Gregory (senior agricultural officer, Jamaica), deputy director of agriculture, Jamaica; R. B. Jagoe (senior botanist (time scale), Federation of Malaya), senior botanist (superscale), Federation of Malaya; G. B. Kennard (marketing officer, British Guiana), senior field officer, British Guiana; E. W. Leach (director of agriculture, Trinidad), director of agriculture, Gold Coast; E. W. Momber (senior agricultural officer, Nigeria), principal agricultural officer, Nigeria; J. T. Moon (senior agricultural officer, Kenya), assistant director of agriculture, Uganda; B. A. O'Connor (entomologist, Fiji), senior entomologist, Fiji; H. T. Pagdon (senior entomologist (time scale), Federation of Malaya), senior entomologist (superscale), Federation of Malaya; M. M. Lucie Smith (agronomist, Trinidad), assistant director of agriculture, Gold Coast; I. R. Dale (senior assistant conservator of forests, Uganda), deputy conservator of forests, Uganda; L. R. Hutson (chief veterinary officer, Antigua, Leeward Islands), deputy director of agriculture (animal husbandry), Trinidad; H. K. Littlewood (deputy director of veterinary services, Nigeria), principal veterinary officer, Western Region, Nigeria; J. McCulloch (senior veterinary officer, Nigeria), principal veterinary officer, Eastern Region, Nigeria; J. K. H. Wilde (chief veterinary research officer, Tanganyika), assistant director of laboratory services, Nigeria; E. Buckley (assistant principal, Technical College, Kuala Lumpur), principal, Technical College, Kuala Lumpur; C. J. Morrison (supervisor grade 2, Agricultural Society, Jamaica), senior soil conservation officer, Jamaica; T. J. Taverner (agricultural assistant, Tanganyika), superintendent of agriculture, Tanganyika; G. W. Arnott, agricultural chemist, Federation of Malaya; P. Class, T. R. Dickinson and D. M. Fordyce, agricultural officers, Federation of Malaya; A. R. Dunbar and W. Hadlow, agricultural officers, Uganda; C. R. Dunton, agricultural officer, Aden; D. F. Edwards and F. Miller, agricultural officers, Gold Coast; R. T. Ellis, plant breeder, Nyasaland; J. T. Hall, agricultural officer, Northern Rhodesia; Miss M. Hayward, plant pathologist, Nyasaland; N. B. Joy, plant pathologist, Tanganyika; A. K. Murray, agricultural officer, Sierra Leone; E. L. Neil, agricultural officer, Nigeria; W. P. Panton, soil chemist (geologist), Federation of Malaya; C. W. R. Pearse, agricultural officer, Tanganyika; S. A. Elks, chemist, Federation of Malaya; E. R. W. Fogden, chemist, Tanganyika; J. A. G. Ellis, assistant conservator of forests, Gold Coast; O. Kerfoot, assistant conservator of forests, Northern Rhodesia; J. F. Watson, assistant conservator of forests, Federation of Malaya; D. A. Eaton, agricultural cocoa survey officer, Gold Coast; G. English, geologist, Nigeria; T. Gorazdowski, fisheries officer, Hong Kong; K. Marshall, prehistorian, Geological Survey Department, Uganda; Miss J. Redwood, assistant adviser on aborigines, Federation of Malaya; D. J. Watson, fisheries officer, Tanganyika.

Announcements

Dr. E. B. Chain, professor of biochemistry and director of the International Research Centre for Chemical Microbiology, Rome, has been elected a foreign correspondent of the Paris Academy of Medicine.

The Dr. W. S. Bruce Memorial Prize for 1952 of the Royal Society of Edinburgh has been awarded by the Joint Committee of the Royal Physical Society, the Royal Scottish Geographical Society, and the Royal Society of Edinburgh, to G. de Q. Robin, for his initiative and resource in carrying out glaciological and biological researches in the Antarctic while with the Falkland Islands Dependencies Survey (1946–47) and with the Norwegian–British–Swedish Expedition (1950–51).

The Secretary of State for War has appointed Mr. H. A. Sargeaunt to be scientific adviser to the Army Council with effect from July 1. Mr. Sargeaunt has held the appointment of deputy scientific adviser to the Army Council since April 1950, and was previously the superintendent of the Army Operational Research Group.

During the recent European Congress for Chemical Engineering, in Frankfurt am Main, the Council, representing seventeen countries, decided to make the congress a permanent annual feature. At the Council's meeting on May 20, a standing committee of four members was elected as follows: Dr. Francis A. Freeth (United Kingdom), M. Jean Gérard (vice-president, Société de Chimie Industrielle, France), Dr. Luigi Morandi, president (Italy), Dr. Herbert Bretschneider, vice-president of the Dechema (Deutsche Gesellschaft fur chemisches Apparatewesen, E.V.), Frankfurt am Main. The next European Congress will take place during June 1953 in Paris.

The twenty-seventh annual conference of Aslib will be held at The Hayes, Swanwick, Derbyshire, during September 19–22, under the chairmanship of Sir Stephen Tallents. The opening address will be given by Prof. T. U. Matthew, professor of the principles of engineering production in the University of Birmingham, who will speak on "The Significance of Information in Present-day Industrial Society". Further information can be obtained from Aslib, 4 Palace Gate, London, W.8.

A meeting was held in the rooms of the Royal Entomological Society of London on March 12, at which, in response to a request from Prof. Grassé and others, the proposal to form a British branch of the Union Internationale pour l'Étude des Insectes Sociaux was discussed. Dr. J. D. Carthy, of Queen Mary College, Mile End Road, London, E.1, has agreed to act provisionally as secretary, and would be glad to hear from any British biologist who would like to join such an organization. If the necessary response is received, steps will be taken to put the organization on a permanent basis and to nominate officers.

A students' essay prize for 1952 has been awarded by the Council of the Institute of Metals to Mr. John C. Wright, of the Development and Research Department, Mond Nickel Co., Ltd., Birmingham, for an essay on "The Metallographic Investigation of Failed High-Temperature Components". In 1953, the Council will award two students' essay prizes of twenty guineas each. The competition is open to student members of the Institute and to associate members of local sections who are eligible for student membership of the Institute, and between the ages of seventeen and twenty-five. The choice of subject is left to the competitors, except that subjects relating exclusively to extraction and ferrous metallurgy are excluded. Entry must reach the Secretary, Institute of Metals, 4 Grosvenor Gardens, London, S.W.1, not later than January 1, 1953.

Erratum. In *Nature* of June 21, p. 1042, in the article on "A Diffraction Corona near the Centre of the Spiral Nebula NGC 4216", by Prof. Bertil Lindblad and Aina Elvius, the blocks for Figs. 3 and 4 have been inadvertently interchanged. The legends are correct as printed.

COSMIC RAYS AND THE SUN'S MAGNETIC FIELD

Apparent Absence of Low-energy Cosmic-ray Primaries

THE purpose of this communication is to examine critically present evidence on the intensity of cosmic rays above and near the top of the atmosphere at high latitudes. It is concluded that low-energy primaries are absent to a significant extent, and that there exists, therefore, near a geomagnetic latitude of 58°, a flattening of the primary momentum spectrum, commonly referred to as a 'knee'.

(*a*) Rocket measurements[1] above the atmosphere at geomagnetic latitude (λ) 58° N. (Gulf of Alaska) yielded a total directional intensity of charged particles of $0 \cdot 29 \pm 0 \cdot 03$ sec.$^{-1}$ cm.$^{-2}$ steradian^{-1} in the vertical direction. The amount of material in the Geiger tube telescope system was 3 gm./cm.^{2} of copper and 0·7 gm./cm.^{2} of aluminium—thus excluding protons[2] of kinetic energy less than 60 MeV. However, the minimum magnetic rigidity of a charged particle for arrival at 58° N. and zenith angle zero is $pc/Ze = 1 \cdot 17 \times 10^9$ V., which corresponds to a kinetic energy of 560 MeV. for protons[3]. Thus, the measured intensity presumably corresponds to the intensity of primary protons (see paragraphs (*f*) and (*g*)) of energy greater than 560 MeV., where the term 'primary' is taken to refer to radiation in the general vicinity of the earth's orbit.

(*b*) Balloon measurements of a similar nature by Pomerantz[4] near the top of the atmosphere at λ = 69° N. (Fort Churchill, Canada) gave a vertical intensity of $0 \cdot 25 \pm 0 \cdot 02$ sec.$^{-1}$ cm.$^{-2}$ steradian^{-1}, a value slightly less than, but within the combination of experimental uncertainties closely equal to, the rocket measurements of ref. 1. However, in the measurements of Pomerantz, the low-energy limit is due to absorption of the residual atmosphere above the apparatus and of the apparatus itself. This may be seen as follows. The magnetic rigidity cut-off at 69° N. and zenith angle zero is $pc/Ze = 0 \cdot 25 \times 10^9$ V., or a proton kinetic energy of 32 MeV. But the residual atmosphere and the balloon-borne telescope totalled about 16 gm./cm.^{2} of air, glass and copper, an amount of material sufficient to stop 130-MeV. protons (cf. table).

Geomagnetic latitude	58°	69°
Measured flux (part. cm.$^{-2}$ sec.$^{-1}$ ster.$^{-1}$)	$0 \cdot 29 \pm 0 \cdot 03$	$0 \cdot 25 \pm 0 \cdot 02$
Min. magnetic rigidity in vertical direction	$1 \cdot 17 \times 10^9$ V.	$0 \cdot 25 \times 10^9$ V.
Corresp. kinetic energy : proton	560 MeV.	32 MeV.
α-particle	670 MeV.	32 MeV.
Instrumental and atmospheric absorption		
Rocket experiment	3·7 gm./cm.^{2}	
Balloon experiment		16 gm./cm.^{2}
Lowest accepted energy (if permitted by geomagnetic field)		
Rocket experiment : proton	60 MeV.	
α-particle	240 MeV.	
Balloon experiment : proton		130 MeV.
α-particle		520 MeV.

(*c*) Thus, from (*a*) and (*b*), it appears that there is a negligible intensity of primary protons in the energy-range 130–560 MeV.—certainly a far lower intensity than would be obtained by extrapolation of the primary spectrum as obtained experimentally in the rigidity range $2 \cdot 6 \times 10^9$–15×10^9 volts[1,5].

(*d*) It may also be noted that the total absorbing material in Pomerantz's experiment, 16 gm./cm.^{2}, is only about one-fourth of the mean free path for nuclear interaction, making the extreme assumption of geometrical cross-section. The attenuation of primaries by processes other than ionization should be small. Thus conclusion (*c*) is not essentially affected by these considerations.

The energy-range of conclusion (*c*) is relatively insensitive to inaccuracies in knowledge of the residual pressure at the maximum balloon altitude. For example, if the minimum residual atmosphere were as great as 20 gm./cm.^{2} instead of the reported value of 11 gm./cm.^{2}, the range of energy would be reduced only slightly, to 170–560 MeV.

(*e*) The above does not exclude, but does tend to make unreasonable, a large intensity of primary protons of energies less than 130 MeV.

(*f*) Various observers[6] have reported that the primary radiation contains 15–35 per cent of alpha-particles. It is therefore of importance to apply similar considerations to these. For alpha-particles, the geomagnetic cut-off kinetic energies corresponding to the previously mentioned magnetic rigidities are 670 MeV. and 32 MeV. at geomagnetic latitudes 58° and 69°, respectively. The rocket apparatus at 58° would exclude alpha-particles of energy less than 240 MeV., and the balloon apparatus and residual atmosphere at 69° would exclude alpha-particles of energy less than 520 MeV. (cf. table).

Thus, it appears that there is a negligible intensity of primary alpha-particles in the energy-range 520–670 MeV. In view of the lower absolute intensity of alpha particles, the narrowness of the deduced energy-range, and possible uncertainties in the balloon altitude, this result is less conclusive than that for protons.

(*g*) Due to the short range of low-energy primary nuclei of Z greater than 2, and their low intensity, the present considerations are of no significance in the determination of a possible 'knee' in their spectra.

The conclusions of this note are in agreement with those of Carmichael and Dymond[7]; but they are perhaps more definitive. We are, however, unable to support the conclusion of Pomerantz[4] that there is no sharp low-energy cut-off in the primary spectrum. Nor can we agree—using the same conventional argument—that the cosmic-ray evidence places as low an upper limit on the sun's magnetic moment as $0 \cdot 6 \times 10^{34}$ gauss-cm.^{3}. The essence of the disagreement is the fact that our measurement of primary intensity at latitude 58° shows that the whole of the increase of intensity observed by Pomerantz between 52° and 69° has already occurred at 58° (see spectral plot in ref. 1). Therefore, the knee of the integral-number spectrum of the primary radiation occurs south of 58° and not north of 69°.

Contradictory evidence has been reported by Staker, Pavalov and Korff[8], indicating an increase at all altitudes by a factor of 2 in the neutron intensity at 69° as compared with 54·7°; however, the extensive neutron measurements made by aircraft by Simpson[9] show practically no increase between the same two latitudes at 30,000 ft. when measured within a short time interval, thus giving support to our conclusions. In fact, recent measurements[10] on the time dependence of the intensity of the nucleonic component lead to an attitude of restraint in the interpretation of intensity differences of the order of 10 per cent, unless measurements are made simultaneously or are normalized by means of an appropriate, continuously operating monitor instrument.

In order to clarify the cause of the 'knee' and in particular to decide between the hypothesis of a solar magnetic field and an inherent change in the form of the primary spectrum due to the mechanism of generation or propagation of cosmic rays, the present measurements should be extended to answer the questions:

(i) Is there complete absence of low-energy primaries at all times? In other words, does the slope of the primary spectrum beyond the 'knee' become zero, or merely very close to zero?

(ii) Do primary alpha-particles and heavier components of the primary radiation exhibit a low-energy cut-off corresponding to the same magnetic rigidity as the proton cut-off ($\sim 1 \cdot 5 \times 10^9$ V.)?

Suitable apparatus which will admit protons of energies down to 5 MeV. is available, but because of the great practical difficulty of getting balloons above a pressure of 10 gm./cm.^{2} it is likely that further extension of the empirical primary spectrum to lower energies can best be done by rocket flights above the atmosphere at northerly latitudes.

Diurnal Variation of Cosmic Rays and the Sun's Magnetic Field

IF the latitude cut-off described in the preceding communication is indeed due to a solar magnetic field, then the value of the solar magnetic dipole moment would be $0 \cdot 65 \times 10^{34}$ gauss-cm.^{3}. (This dipole moment can be expressed as $8 \cdot 75 \times 10^9$ V. × (sun–earth distance)^2 and corresponds to an empirically observed[1] proton cut-off momentum at the earth's orbit of $1 \cdot 5 \times 10^9$ eV./c.) In addition, such a magnetic dipole field is expected to lead to a diurnal variation[1] of the low-energy part of the primary cosmic radiation incident on the earth. (In particular, the allowed solar cone would be completely open for particles of magnetic rigidity of $8 \cdot 75 \times 10^9$ V. and completely closed for particles of $1 \cdot 5 \times 10^9$ V. ($= (1 + 2^{1/2})^{-2} \times 8 \cdot 75 \times 10^9$ V.) according to the Störmer theory of the allowed cone.) The experimental absence[3] of this diurnal variation has been used for supporting the view that the sun's field must be at least an order of magnitude smaller than the value given above. (This would then be in accord with modern astronomical measurements of the Zeeman effect of solar absorption lines which give a magnetic field essentially zero[4].)

It may be perfectly true that the sun has no appreciable dipole moment, and we do not wish to imply that this is not the case. However, without questioning the validity of the conventional arguments employed, we merely wish to show here that their correct application does not lead to the same conclusion, since even with a magnetic moment of magnitude sufficient to explain the latitude cut-off, the diurnal variation to be expected would be so small as to be practically undetectable. This assertion is based essentially on a detailed recalculation of the diurnal variation using the basic results of Kane, Shanley and Wheeler[5], and the explicitly and very clearly presented methods of Dwight[6]. In particular, we make use of a dipole moment of $0 \cdot 65 \times 10^{34}$ (instead of 1×10^{34}) gauss cm.$^{-3}$ and a primary rigidity spectrum corresponding to the empirically observed integral spectrum[1,6] which has an exponent of $- 1 \cdot 1$ in the region sensitive to latitude (instead of $- 1 \cdot 75$). Both changes tend to reduce the diurnal variation.

(*a*) In order to deal with an actual situation, we will attempt to analyse the experiments of Bergstralh and Schroeder[3] performed at lat. 56°, near the optimum latitude for observing the diurnal variation[6]. To obtain the maximum diurnal spread, one first computes the exact shape of the diurnal variation for a particular solar magnetic moment and rigidity spectrum[6] (cf. columns (3) and (4) of the table).

DIURNAL VARIATION OF PRIMARY COSMIC RADIATION AT LAT. 56° Calculated for various values of the solar magnetic moment and the exponent of the integral primary rigidity spectrum

Solar magnetic moment (gauss-cm.^{3})	Fill-up, φ, of trapped orbits (per cent)	Max. diurnal spread for exponents of −1·75 and −1·1 of primary rigidity spectrum with orbits empty		with orbits filled	
		−1·75	−1·1	−1·75	−1·1
		per cent	per cent	per cent	per cent
$1 \cdot 0 \times 10^{34}$	92*	92·5†	75	7·4	6
$0 \cdot 65 \times 10^{34}$	95‡	60‡	55	3	2·5
$0 \cdot 42 \times 10^{34}$	96·5*	45†	35	1·6	1·2
(1)	(2)	(3)	(4)	(5)	(6)

* Deduced from Fig. 4 of ref. 5;
† Scaled from Fig. 3 of ref. 2;
‡ Interpolated values.

(*b*) It is next necessary to take account of the filling-up of forbidden orbits (that is, 'trapped' orbits which do not come from infinity and are therefore outside of the allowed cone). Alfvén[7] first pointed out that these orbits might be filled up to an appreciable extent with particles which, although forbidden to enter them, have been scattered by the earth's magnetic field into trapped orbits. More refined calculations have been performed by Wheeler *et al.*[5] for two solar moments (1×10^{34} and $0 \cdot 42 \times 10^{34}$ gauss-cm.^{3}). By considering the scattering effect of the earth's field which, so to speak, 'punches a hole' into the magnetic screen produced by the sun, and taking into account removal of these particles by collisions with the earth and other planets, they have computed the percentage, φ_{diff}, to which the forbidden orbits are filled up, as a function of the magnetic rigidity of the primaries. From their results we have deduced the values of φ in column (2) of our table by some numerical integrations and a reasonable interpolation. It is to be noted that the 'average' φ of 90 per cent used by Dwight[2] gives values for the diurnal variation which are too high by a factor of 2–3 for the lower values of solar magnetic field. (This sensitive dependence on φ arises because the values of actual diurnal variation in columns (5) and (6) are obtained by multiplying (3) and (4) by $(100 - \varphi)/100$.)

(*c*) The final value for the calculated maximum variation, 2·5 per cent, must be reduced somewhat when comparing it with experimental results; a 'smearing-out' of the peaks of the variation occurs, as it is necessary to average over time intervals sufficiently long to give a statistically significant number of counts.

(*d*) We must therefore compare a calculated variation of 2 per cent (rather than 9 per cent) with the experimental value of 0 ± ~1 per cent[3]. We do not believe that they differ significantly.

(*e*) In combination with the conclusions of the preceding communication, it would appear then that none of the present ***experimental*** results in cosmic rays can be used reliably as evidence against the existence of a solar dipole moment up to a limit of about $0{\cdot}65 \times 10^{34}$ gauss-cm.^{3}.

The present investigation is perhaps of more than academic interest since, on one hand, it has been suggested that the sun's magnetic field undergoes a periodic variation[4]; on the other hand, the validity of drawing any conclusions about a general magnetic field of the sun from measurements of the Zeeman effect in the turbulent absorbing regions of the solar atmosphere has been questioned[4]. It is of importance, therefore, to examine critically all cosmic-ray evidence which purports either to deny or affirm a solar magnetic field.

Additional Considerations. The calculated diurnal variation can be reduced even further when it is noted[5] that the population of the trapped orbits is increased if planets, in particular Mars and Venus, possess a magnetic moment, as appears very reasonable. In addition, further holes can be punched in the magnetic screen by solar corpuscular streams carrying magnetic fields outward through the planetary system. Their rate of occurrence is appreciable compared to the time constant of the trapped orbit particles, which is about 5,000 years[5]. By means of these additional influences, particles may be admitted into the vicinity of the earth which have energies lower than the helio-magnetic cut-off. Such particles, which could enter the earth only at high latitudes, have not been observed in appreciable numbers. This objection may perhaps be met by noting that (i) they might be few in number originally; and (ii) if admitted they will be removed very quickly through ionization loss in interplanetary matter, an effect which can be neglected at higher energies[6]. (For example, a proton having a rigidity of $0{\cdot}5 \times 10^9$ V. possesses kinetic energy of $0{\cdot}12 \times 10^9$ eV., corresponding to a range of 10 gm./cm.^{2}. The average[6] path-length is 25 gm./cm.^{2} and may well be longer at low energies.)

These considerations again point to the importance of conducting cosmic ray measurements at high altitudes and high latitudes on a continuous basis, preferably correlated with similar measurements at intermediate latitudes.

AN UNUSUAL TRANSFORMATION OF ISOMERIC FORMS OF TETRAACETYL D-RIBOFURANOSE

By Dr. JOHN DAVOLL* and GEORGE BOSWORTH BROWN

Sloan-Kettering Institute for Cancer Research, New York

AND

DONALD W. VISSER

Department of Biochemistry and Nutrition, University of Southern California School of Medicine, Los Angeles

1 : 2 : 3 : 5-Tetraacetyl D-ribofuranose was first prepared by Howard, Lythgoe and Todd[1] by hydrogenolysis of 1 : 2 : 3-triacetyl 5-trityl D-ribose, followed by acetylation of the resulting 1 : 2 : 3-triacetyl D-ribose. The compound had melting point 58°, $[\alpha]_D^{15°}$ + 20° (c = 0·645 per cent in chloroform). Later, Bredereck and Hoepfner[2] obtained a tetraacetyl D-ribose of melting point 56°, $[\alpha]_D^{20°}$ − 3·6° (in methanol) by treatment of 1 : 2 : 3-triacetyl 5-trityl D-ribose with acetyl bromide in acetic anhydride solution. There is no reason for doubting the identity of this compound with that obtained by Howard, Lythgoe and Todd. In 1950, Zinner[3] reported that direct acetylation of ribose yielded a mixture of 1 : 2 : 3 : 4-tetraacetyl D-ribopyranose and a new tetraacetyl D-ribofuranose, melting point 82°, $[\alpha]_D^{24°}$ − 12·6° (c = 12·83 per cent in chloroform), $[\alpha]_D^{24°}$ − 15·4° (c = 7·227 per cent in methanol), which was named 'β-tetraacetyl D-ribofuranose'. The present communication is concerned with its relationship to the previously known isomer.

In 1949, one of us (J. Davoll) prepared several batches of tetraacetyl D-ribofuranose by Bredereck and Hoepfner's method. While the first three of these preparations had melting point 56–58°, the fourth run yielded a compound of melting point 85°, $[\alpha]_D^{23°}$ − 12° (c = 2 per cent in chloroform), $[\alpha]_D^{23°}$ − 13·5° (c = 5 per cent in methanol). This compound had the composition of a tetraacetyl ribose (found: C, 49·25; H, 5·75; acetyl, 53·9; calc. for $C_{13}H_{18}O_9$: C, 49·05; H, 5·7; acetyl, 53·9 per cent) and proved to be identical with a specimen of 'β-tetraacetyl D-ribofuranose' prepared by Zinner's

Changes in specific rotation accompanying transformation of the form of melting point 56° to that with melting point 85° in methanolic solution

method[3]. Its furanose structure was proved by its conversion, through the acetochloro compound, to adenosine[4], in yields similar to those obtained from the tetraacetyl ribofuranose of melting point 56–58°.

It was now found that the melting points of samples of the earlier preparations had risen to 85°, and it proved impossible to prepare the form of lower melting point. When a sample of melting point 56°, obtained from Prof. Todd's laboratory, was exposed to the air in a laboratory inoculated with the form of higher melting point, the crystals rapidly became opaque and their melting point was then found to be 85°. (We wish to thank Dr. S. Trippett for providing this sample. Prof. Todd, whom we wish to thank for his criticisms of the manuscript, has informed us that the transformation to the isomer of higher melting point has now been observed at Cambridge.) Dr. Visser has studied the catalytic effect in the solid state under more controlled conditions. Inoculation of a dried sample (1 gm.) of melting point 57° with 1 mgm. of that with melting point 85° (obtained from the Sloan-Kettering Institute) raised the melting point to 75–77° within two hours, and to 77–79° overnight; this was further raised to 84–85° by recrystallization. An odour of acetic acid was noted during the transformation.

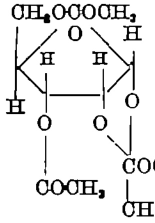
Dr. Visser has also shown that the catalytic effect operates in methanolic solution. Immediately after opening the sample of the isomer of melting point 85°, a previously prepared methanolic solution (c = 2·94 per cent) of the isomer of lower melting point in a polarimeter tube was inoculated with a minute amount of the higher melting form. The subsequent changes in optical rotation of the solution, confirmed in a duplicate experiment, are shown in the accompanying graph.

A satisfactory explanation of these observations must account for: (a) a structural change in the molecule to account for the alteration in optical rotation; (b) the catalytic effect, in solution and in the solid state, of the form of higher melting point; and (c) the complexity of the change in specific rotation shown in the graph, which indicates the presence of at least three molecular species.

If the isomer of melting point 56° is denoted by A, and that of melting point 85° by B, the catalytic effect might be explained by a reaction (probably involving acetyl migration) between A and B to give a compound which might then become rearranged and dissociated to give two molecules of B:

$$A + B \rightarrow A\,.\,B \rightarrow B + B.$$

We have been unable to determine the nature of the difference between the two isomers. The closeness in specific rotation of the two forms, and the facility of the conversion of the 56° into the 85° isomer, are against simple α, β isomerism. It is also possible that one form has the orthoacetate anhydride structure shown (which, like the acetylated carbohydrate methyl orthoesters[5], might be expected to give rise to a normal acetyl glycosyl halide), though this structure is difficult to reconcile with the stability of both forms to water and ethanol. Only one compound of the same type appears to have been prepared, namely, an amorphous octa-acetyl maltose[6], the properties of which have not been reported.



The difficulty of again obtaining the lower melting isomer in either of these laboratories has prevented further study of this remarkable transformation.

This investigation was supported by grants from the National Cancer Institute, of the National Institutes of Health, Public Health Service, and from the Atomic Energy Commission, Contract AT(30–1)–910, to the Sloan-Kettering Institute, and from the United States Public Health Service to the University of Southern California.

MANAGEMENT IN SCOTLAND

IN a paper submitted to the Scottish Management Conference which was held at Gleneagles during April 25–27, Mr. B. A. C. Hills, controller of S. Smith and Sons, Ltd., suggested that what is most urgently needed in industry to-day is the realization that behind high-sounding labels lie ordinary actions which not only can be applied to businesses but also should be. Line production, for example, is too often only associated with mass production of cars and refrigerators, whereas it could, in fact, be used in the majority of factories.

The principles of economic manufacture demand the maximum output of finished goods from the minimum total resources in material, labour, equipment, time and money, or, more simply, the reduction of costs. The main principles should be, first, the need for the constant inter-relation of all costs; a reduction in total costs may involve a deliberate increase in some items, such as the use of larger components, for example, to reach a higher degree of standardization. Secondly, the standardization of materials, sizes and shapes of components; excessive variety is one of the most common causes of high costs. Thirdly, a higher degree of mechanization. There should be a national policy to transfer labour to the production of capital goods. Fourthly, the establishment of methods-time measurement; this is a new and potent weapon in the achievement of economic manufacture which will be of particular value to the medium-sized firm not necessarily engaged in large-scale production. Fifthly, the indirect operation should be eliminated or reduced to the minimum; the siting of machines in correct sequence, instead of departmentally, can also help to reduce the indirect operation. Sixthly, a sales and design policy should be employed to produce the degree of variation in quantitative demand and of variety of products needed to keep the flow of work as regular as possible. Lastly, Mr. Hills suggested that use should be made of control data to see that costs are kept within bounds.

In his paper on the human factor in management, Sir Richard Lloyd Roberts appealed to management to "identify itself with the inevitable and welcome the employees genuinely as associates and collaborators in the joint industrial enterprise". This change in outlook is necessary because, for the first time, the problem of industrial management is now set against a background of free men in a free society.

Surveying existing man-power situations, Sir Richard suggested that personal fitness should be the only test for employment and not some arbitrary age; existing apprentice arrangements should be reviewed and better training facilities should be provided at all levels, including the young manager.

For practical application, the new concept of the status of the employee requires, first, the careful selection and placing of the individual and the provision of an induction course on entry into the firm. Secondly, his interest in the enterprise should be secured by explaining the problems involved in production, even to the extent of making him aware of the firm's plans and policies. Thirdly, working to create this new 'climate' involves management in a serious educative campaign to combat the misunderstandings that exist about the structure of industry, the role of the investor, the reasons for profit, the responsibilities of directors and management. Foremen, no less than management, must change their traditional attitudes and methods of control. Much-needed attention is now being given to the selection and training of foremen; but there is too much hesitancy about giving them adequate staff status and remuneration in relation to the men under them.

Sir Richard forecasts that piecework will ultimately disappear since its appeal is to the financial cupidity of the individual and, in the role of collaborator, this spur will not be necessary to ensure a fair day's work. The trade unions have a share in the hindrance of the full development of the human factor. Their conventional belief is that the natural alliance of any group of work-people in a given firm is with their fellows of the same craft or industry employed elsewhere. This attitude is understandable in the light of past experience; but under modern conditions it should be recognized that the full value of any human factor can only be fostered in the individual works, factory or mine by the collaboration between man and management in that unit.

T. H. HAWKINS

LYSENKO'S LATEST DISCOVERY—THE CONVERSION OF WHEAT INTO RYE, BARLEY AND OATS

By PROF. P. MAHESHWARI
University of Delhi

A FEW months ago Academician T. D. Lysenko produced an interesting paper entitled "New Developments in the Science of Biological Species", an English translation of which has been recently published by the Foreign Languages Publishing House, Moscow[1].

The first half of the paper is devoted to a consideration of the concept of genus and species. In the latter half Lysenko first refers to V. K. Karapetian's[2] observation of 1948 that if 28-chromosome durum wheat (*Triticum durum*) is sown late in the autumn some of the plants are converted in two or three generations into 42-chromosome soft wheat (*T. vulgare*). This prompted Russian workers "to search for grains of soft, 42-chromosome wheat in the spikes of experimentally grown durum wheat. As a result, individual grains of soft wheat were quite easily observed in the spikes of durum wheat, i.e., *grains of one botanical species were found in the spikes of another species*" (italics mine).

That the abnormally arising grains really belonged to *T. vulgare* was confirmed by sowing the seeds which "produced, *as a rule* (italics mine), soft wheat plants". It is not mentioned as to what they produced in the remaining cases; but it may be presumed that they either did not germinate or produced durum plants.

Encouraged by this discovery, Russian botanists instituted in 1949 a vigorous search for rye grains in wheat spikes in the fields of the foothill districts sown with winter-wheat. Their efforts were amply rewarded. "V. K. Karapetian, M. M. Yakubtsiner, V. N. Gromachevsky and a number of other research workers as well as a number of agronomists and students found single grains of rye in durum- and soft-wheat spikes, i.e., in the spikes of two wheat species which grew in the fields of various foothill districts. Over 200 such grains of rye were found in 1949. . . . From these grains of rye, which had developed in spikes of durum and soft wheat, a diversity of plants was grown. These plants, *with few exceptions* (italics mine), were nevertheless typical rye. Only in a very few cases were wheat plants obtained from ryelike grains." No mention is made of the range of variability in the offspring of the rye-like grains, nor are we told the type of wheat—$2n$, $4n$, or $6n$—which arose from them in exceptional cases.

"In all the above cases where grains of one species of plant were found in spikes of another species neither the plants themselves nor their threshed spikes showed any signs whatever of being intermediate forms. They seemed to be typical, ordinary spikes of durum or soft wheat. But the internal state of these wheat plants was no longer the usual one, was no longer qualitatively homogeneous in respect to species."

Other interesting facts follow. Plants of *Avena sativa* were observed to bring forth individual grains of *A. fatua*. Branched wheat (*Triticum turgidum*), grown on the experimental plots of the Lenin Academy of Agricultural Sciences of the U.S.S.R. and in a number of other localities, showed "admixtures of soft and durum wheat, oats, 2- and 4-rowed barley and also spring rye". It is stated that the original source of these admixtures was the branched wheat (*Triticum turgidum*) itself, and that this was not a consequence of the use of impure seed.

"In 1950 it was discovered in several cases that barley plants which were growing as an admixture in branched wheat crops had developed from grains which in external appearance could not be distinguished from branched wheat grains."

It is emphasized that these new facts were obtained "*in a systematic way* or as the result of *a systematic search*". The supposition that the seeds may be of hybrid origin is rejected, and it is stated that similar results can be obtained "by cultivating plants specially sown under experimental conditions for this purpose".

The paper contains a good deal more, mostly in the nature of the usual diatribe against Malthus and in praise of Timiryazev and Michurin. Stalin's name is also mentioned; but leaving the political issue aside and taking only the scientific part into consideration, the present position is considerably different from that a few years ago when stray rye plants were mentioned as appearing in wheat fields. Geneticists in Britain and the United States explained such an occurrence as caused by sowing mixed seed. Now our Russian colleagues claim that there is no question of mixture, for rye grains are said to have been found *within* wheat spikes and "could not possibly have been introduced into these spikes from without by either birds or man in any other way".

The possibility of hybridization or the influence of foreign pollen is rejected in the following words: "The supposition that these seeds might be of hybrid origin also goes by the board. It is a known fact that wheat can be crossed with rye, though seldom. However, in these cases the product obtained is an obvious rye–wheat hybrid which can readily be distinguished from wheat and rye by its external appearance. Besides, rye-wheat hybrids, as a rule, are self-sterile; they yield no seeds unless they are pollinated with the pollen of one of their parents, preferably the wheat. In the case at hand the grains of rye from the wheat spikes produced ordinary rye plants with normal fertility. The said plants manifested no hybrid properties whatever".

Academician Lysenko thinks that so far as plants are concerned the problem of speciation has therefore been solved, and a change in environment is the key to its solution. With regard to animals also he is quite hopeful as the following quotation will show: "We do not yet have the data essential to demonstrate how species are formed in the animal world. But we may rest assured that before long the development of the theory of Michurinist biology will make it possible to accumulate data also for zoological objects analogous to the data taken from the world of plants".

This much about Lysenko's science. As the result of the work of Kihara, Sears and others, enough is, however, known of the cytology of wheat, rye, barley and oats to make one extremely sceptical of his claims about the conversion of one into another. Some of these doubts are mentioned below.

(1) Lysenko says that grains of soft wheat found in spikes of durum wheat *as a rule* produced soft wheat plants. What did they produce in other cases?

(2) How did wheat plants arise from a few of the rye-like grains? Does this mean that rye can in turn become converted into wheat? Were these wheats diploid, tetraploid or hexaploid?

(3) Since rye has 14 chromosomes, by what method could a vulgare wheat ($2n = 42$) give rise to rye? Not only is the number of chromosomes different in the two cases but also the morphology of the chromosomes. For example, pines have $n = 12$ chromosomes and so have the lilies; but it is not possible to convert one into the other.

I think that there is no possibility whatever of changing tetraploid wheat into a hexaploid type as the result of environmental influences only, although the Russians claim to have accomplished it many years ago. Conversion of wheat into rye, barley and oats is fantastic and even more unbelievable. To understand this, we must have a mechanism for the deletion of the three genomes, *A*, *B* and *D*, present in *T. vulgare*, or *A* and *B* present in the emmer wheats and the appearance of a new rye, barley or oat genome. This, most people will agree, is not possible by environmental changes.

However, this is not the first time that such reports have appeared. Many years ago Virgil and Pliny wrote how farmers planted wheat and barley only to discover to their annoyance that some of the seed produced wild oats. Thomas Johnson[2] in 1633 reported the occurrence of a grain of oat in an ear of wheat, and Ole Worm[3] in 1655 claimed to have seen a rye grain in an ear of barley.

Most botanists outside the U.S.S.R. are inclined to dismiss all such reports as errors of observation or as faked. Judging from the exaggerated nature of Russian reports and the lack of proper data for an evaluation of their claims such a surmise is not unnatural. However, if rye grains do occasionally occur in wheat spikes, the only possible explanation is that the stigmas of some of the wheat flowers become pollinated by rye pollen. In most cases, perhaps, such pollen tubes would fail to reach the ovules. If they did it is possible that either the eggs may be stimulated to develop parthenogenetically; or there is a fusion of the female nucleus belonging to the wheat parent with the male nucleus contributed by the rye parent, resulting in hybrid progeny; or the male gamete develops 'androgenetically' inside the embryo sac, seed coat and pericarp of wheat. In the third case the offspring would be a haploid rye, but if chromosome doubling took place at some stage in embryogeny the mature grain would produce a normal diploid rye plant. The so-called 'conversion' of wheat into barley or oats could also be understood as occurring in the same manner.

Such 'androgenesis' is already known to occur in *Nicotiana* and *Crepis* (see Maheshwari[4] for references; also Darlington and Mather[5]), and the work on *Crepis* was done by a Russian botanist, Helen Gerassimova[6]. Lysenko is either not acquainted with the literature on cytology, embryology and genetics or is unable to take this into account because of a blind faith in environment.

It is hoped that other botanists who see this note will express their opinions on this wheat–rye conversion and that meanwhile Russian botanists will themselves present a cytological analysis of the converted wheat or rye plants.

MICRO-MAGNETIC VARIATIONS DURING THE SOLAR ECLIPSE OF FEBRUARY 25, 1952

By Prof. N. F. ASTBURY

University College, Khartoum

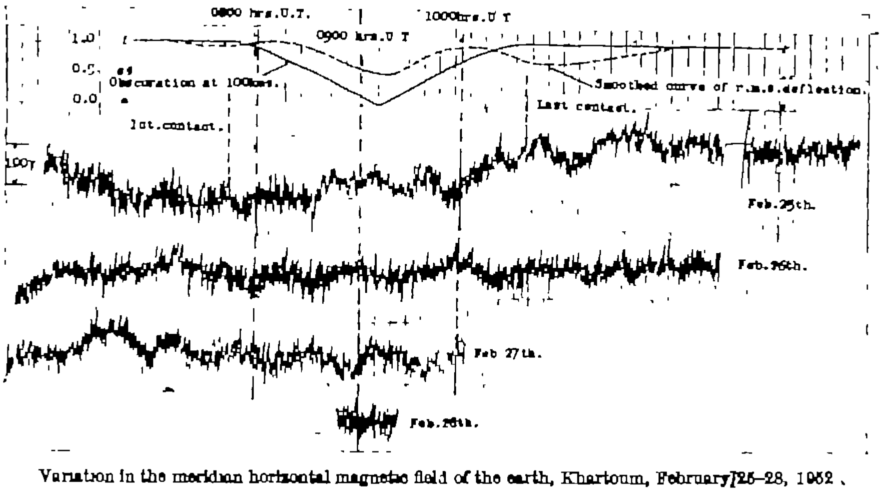
THE occurrence this year of a solar eclipse the totality zone of which crossed the magnetic equator provided a special opportunity for the observation of variations of small amplitude in the earth's magnetic field. During the Second World War, I was able to observe (but not to publish for security reasons) variations in the earth's field in the frequency-range 0·005–200 c./s. in northern auroral latitudes. In the stress of war-time conditions it was not possible to investigate causes of or possible cyclic changes in these variations, so that the opportunity of examining corresponding phenomena near the magnetic equator, especially during a total eclipse, was particularly interesting.

The observations planned for the total eclipse of February 25 were necessarily very simple, because of the short time available for preparations. The plan was to observe changes in the meridian horizontal component of the earth's field, and the site chosen was in the grounds of University College, Khartoum, about 5 km. north-east of the centre line of the ground totality zone. Through the kindness and great expedition of the Royal Naval Scientific Service, recording gear was sent to Khartoum and put into working order a few days before the eclipse. The detector used was a coil of about two metres diameter, carrying 540 turns, set up in a vertical plane with its axis in the magnetic meridian. This was connected to an integrating D.C. amplifier and to a low-frequency thermionic amplifier with a frequency range of 5–200 c./s. The time-constant of the D.C. amplifier and associated circuits was about 40 sec., so that its response to a sinusoidally varying flux was a maximum for changes of about this period, falling to about 90 per cent for periods of 5 sec. and to about 60 per cent for periods of 200 sec. For signals near the optimum period a displacement of 1 mm. on the recorder trace corresponded to a field change of 10 gamma. Such preliminary experiments as were possible showed at once that while it would be satisfactory to work with the D.C. gear in this condition, heavy and variable industrial interference made the operation of the low-frequency amplifier unreliable. For the eclipse work this had therefore to be abandoned, but it will be set up outside the town later.

For the eclipse observations, the recorder was run with a paper-speed of 1·25 in. per min. to secure high resolution. Observations were started half an hour before sunrise (0330 hr. U.T., 0530 hr. L.T.) and were continued until half an hour after sunset. The record showed a marked change in character during the eclipse, variations of amplitude about 100 gamma and period 20–30 sec. giving way to disturbances of half the amplitude or less and of much longer period. The concise presentation of such a record is a matter of some difficulty, and two methods have been attempted. In one, the mean square deflexion has been computed for every four-minute interval of the record, and the resulting curve smoothed. In the other, a mechanical copy has been made of the whole record in which the paper-speed has been reduced to about one inch per minute, the deflexion being at the same time amplified about one and a half times. The accompanying chart is a copy of such a reduced record, together with the smoothed curve of root-mean-square deflexion and the obscuration curve for the 100-km. level. On the same chart are reproduced copies of control records taken on succeeding days at relevant times.

On the day of the eclipse, there is a region of minimum disturbance about ten minutes after totality, and although the descent to the minimum follows in a general way the occultation of the sun's disk, the restoration is prolonged ; and it is not until four or five hours after the last contact that the disturbances have built up to their pre-eclipse level.

Concurrently with these observations, ionospheric recordings were made on the same site by Mr. C. M. Minnis and Mr. Clarke, of the National Physical Laboratory, using an automatic recorder of N.P.L. design. While the full analysis of both magnetic and ionospheric records has yet to be completed, there can be little doubt that changes in the variations of the horizontal magnetic field at the earth's surface were



Variation in the meridian horizontal magnetic field of the earth, Khartoum, February 25–28, 1952.

associated with changes in the ionosphere. It is suggested that the magnetic variations are due largely to plasma oscillations in the lower levels of the ionosphere.

Subsequent 24-hr. recordings taken with a paper-speed of 1 in. per hr. have shown the existence of a marked diurnal effect, together with a curious major disturbance about an hour before sunset. It is planned to extend the work to include the vertical component of the field and to make continuous ionospheric recordings over the more significant times, and a full report will be published elsewhere. [April 27.

RESEARCH COUNCIL OF ISRAEL

ANNUAL REPORT FOR 1950–51

THE second annual report of the Research Council of Israel, covering the year ended March 31, 1951, has recently been published*. In place of the original five advisory committees, committees have now been established for fundamental research (including the utilization of the natural resources of Israel), chemical industry, textile industry, agriculture, nutrition, food industry, and building (including roads). The membership of these committees is given, with lists of publications and research papers issued during the year.

The work of the Geological Survey has been facilitated by the establishment of a palæontological laboratory. The search for additional sources of water has continued, deposits of peat have been discovered and the search for petroleum reserves continued. The Citrus Concentrates Producers Association completed successful pilot-plant trials on a process for the preparation of dry pectin of high jelly units from orange peel without the use of organic solvents, and has used ion-exchange resins to obtain a completely demineralized sugar syrup from limed citrus-peel juice. Research on pectolytic enzymes is a major activity in this laboratory, while the Ceramics Research Association has overcome difficulties experienced in slip casting due to the poor quality of the plaster by changing the conditions of fixing. The Textile Research Association has continued work on the shrink-proofing of wool with acid bromates. Medical research has included studies of the mechanical fragility of erythrocytes in the presence of sulpha-drugs and of the intestinal flora of the newly born. Biological research has covered ticks and tick-borne diseases, vole research and the mode of action of germination inhibitors. The hydrochemistry of the Sea of Galilee was studied to determine the origin of the salts in the Dead Sea, and satisfactory yields of naphthenic acids have been obtained by oxidation of kerosene containing 18 per cent of aromatic acids after removal of the latter with sulphuric acid. A survey of the source of raw materials for the manufacture of cellulose has been undertaken, and a study made of micro-organisms responsible for the retting of flax.

Building research has been done on a number of topics which include: a study of the influence of all types of roof structures and of the effect of the design, finish and material of wall structures on the internal climate; the efficiency of housing schemes for immigrants; solar heating of domestic water supplies; and the ageing of bitumen. Dew and water condensation in upper layers of soil and evaporation from open surfaces have also been investigated, solar radiation in the visible and infra-red regions was being measured, and field trials made of a number of fibre-yielding plants. A study of the population dynamics of the Mediterranean fruit fly, *Ceratitis capitata*, was initiated and also of the biological factors affecting the yield of legumes, while investigations of weeds and a study of the nutritional deficiencies of fruit trees were continued.

AMERICAN PHILOSOPHICAL SOCIETY

REPORT FOR 1951

THE year book for 1951 of the American Philosophical Society covers the year ended December 31, 1951*, and, besides a brief history of the Society by E. G. Conklin, biographical memoirs, lists of members and the auditor's report, includes the customary reports of the standing committees on finance, the library, meetings, publications and research. The report on research, which occupies most of the year book, details the ninety-six grants, totalling 85,305 dollars, which were awarded from the Penrose Fund during the year and gives an analysis of the distribution of grants from this Fund by subjects during 1949–51. Also detailed are five grants, totalling 9,950 dollars, from the E. R. Johnson Fund, two, totalling 4,750 dollars, from the J. Daland Fund for Research in Clinical Medicine, two from the Miclaux Fund, and twenty-eight, totalling 30,245 dollars, from the Reserve Fund for Post-war Expenditures, all of which were for research.

Among the more detailed of the reports from recipients of grants which are included (arranged alphabetically under subjects) in the report, mention may be made of that by H. Friedmann on the life-histories of the honey-guides (Indicatoridæ) and the parasitic weaver-birds (Ploceidæ) of Africa; S. M. Rose's study of induction of regeneration in limbs of lizards; C. A. G. Wiersma's investigation of the patterns of innervation of the legs in the higher crustacea, with special emphasis on the inhibitory innervation; H. E. Evans's taxonomic and biological study of the spider wasps of Mexico belonging to the sub-family Pompilinæ (Hymenoptera, Pompilidæ); W. Hovanitz's amphi-Atlantic study of *Colias hecla*, *Colias nastes* and *Colias palæno* and J. A. G. Rehn's detailed field study of the Orthoptera of the United States.

G. L. Kreezer reports on the development of methods for the determination of the components of biological systems on the basis of the mathematical analysis of transient response curves; D. C. Smith on studies in Bermuda on the thyroid glands of the parrot fish; C. L. Markert on the biochemical basis of cell differentiation; H. N. Andrews on the anatomy of *Botryopteris*; W. R. Taylor on his survey of the marine algæ of Bermuda; L. M. Langdon on a comparative survey of inflorescence characteristics in the Castaneæ; and H. P. Hansen on the study of post-glacial forest migrations and climate in Western Canada and Alaska by means of pollen analysis of peat sections. Reports are also included of W. H. Camp's study of the relative virulence of beech bark disease on the several types of forest beech in eastern Canada and Maine; of B. Howe's investigation of caves, shelters and other sites where it is expected that Neolithic, Mesolithic and Palæolithic remains are to be found in stratigraphic relation; of E. Murray's case study of colour-vision deficiency; and R. B. Singer's clinical and physiological investigation of disturbances of the acid–base balance of the blood, with particular reference to the effects of intravenous alkalinizing or acidifying solutions.

METROLOGY LABORATORY OF THE COLLEGE OF TECHNOLOGY, BIRMINGHAM

IN the College of Technology, Birmingham, the Production Engineering Section of the Department of Mechanical Engineering for the past five years has been developing the teaching of production techniques, particularly in the fields of machine tools, jigs and tool design, and fine measurement. In the last-named case, the new Metrology Laboratory of the College, which has been equipped at a cost of nearly £5,000, is now complete.

The functions of this Laboratory are threefold. First, it provides students with an opportunity for undertaking experimental work, and determining fine measurements using modern general and specialized equipment, the laboratory work being closely related to the lecture course. Secondly, the Laboratory is intended to provide local industry with an approved centre in which specified gauges may be measured. This project should be of particular interest to small engineering firms with only limited measuring equipment. In order to achieve this aim, the layout of the Laboratory has been supervised by the Metrology Division of the National Physical Laboratory, which has certified the equipment provided as satisfactory for an approved gauge testing centre. Further, a member of the staff who has maintained contact with the National Physical Laboratory during the development stage has qualified to act as the authorized supervisor. The gauge testing scheme is an arrangement whereby an educational establishment possessing specified measuring equipment may undertake the inspection of certain classes of gauges on behalf of the National Physical Laboratory. Inaugurated by the Ministry of Education, the scheme has the support of the Ministry of Supply, and as a result it covers the same classes of work for the Aeronautical Inspection Department. The Metrology Laboratory is authorized to undertake the inspection of parallel plain plug and parallel ring gauges; taper plain ring gauges; parallel plain gap gauges; taper plain gap gauges, and simple plain length, height, depth and thickness gauges; parallel screw plug gauges up to 4 in. diameter, of Whitworth, metric and B.A. forms of thread; profile gauges; and simple angle gauges.

The third function of the Laboratory is that its equipment, which is in excess of the requirements of the National Physical Laboratory scheme, has been designed to promote additional facilities for research — a relatively new venture, upon which staff members are now engaged. These investigations are concerned with the study of the characteristics of fine metallic surface-finishes with reference to mechanical methods of production, which has led to further studies of the influence of surface finish on friction and wear.

The Metrology Laboratory is electrically heated and thermostatically controlled at 68° F. (20° C.). Fluorescent lighting is installed. The majority of the equipment, which is almost exclusively of British design and manufacture, has generally been purchased; but certain firms have presented apparatus to the College. Apart from the essential standard gauges and measuring tools, the equipment includes measuring machines for the determination of errors in screw threads, including optical projection apparatus; a 7–36 in. end-measuring machine with accessories; and a taper diameter-measuring machine, all of which are based on National Physical Laboratory designs. Comparator-type measuring equipment representing mechanical, electrical, pneumatic and optical forms of operation are available. The issue of "Acceptance Test Charts for Machine Tools", prepared by the Institution of Production Engineers, and published in collaboration with the Institution of Mechanical Engineers, has led to the provision of equipment necessary for machine-tool alignment-tests. This includes optical instruments such as the 18-in. 'Microptic' auto-collimator, reading directly to 0·5″ of arc, and an alignment telescope and target, reading to 0·0005 in., both manufactured by Messrs. Hilger-Watts, Ltd. A standard 'Angle-Dekkor', reading to 1′ of arc, is also available. Experimental apparatus for preliminary surface-alignment tests has been constructed in the Laboratory, but work of an advanced nature is carried out on standard machines in the various machine-tool laboratories. A tool-room microscope with accessories, by Messrs. Cooke, Troughton and Simms, Ltd., has been provided for the measurement of angles, thread forms, linear displacements, and for the comparison of enlarged projected images.

Surface-texture measurements may be carried out using the latest Taylor Hobson 'Talysurf' Model 3. This machine measures the roughness of surfaces by traversing a stylus across the surface and electrically amplifying its movements. The result of the examination may be shown in the form of a graph indicating the nature of the surface undulations. Alternatively, an average number may be recorded indicative of the degree of roughness. A model of the well-known 'Tomlinson' mechanical surface-recorder, in which a trace is made on a smoked glass, provides an alternative method of surface measurement.

As the Laboratory is for the use of senior students taking the craftsman's course, as well as for students in advanced professional courses, apparatus in the form of gauges in common use has been constructed for examination. All experimental work is based on instruction sheets giving details of the equipment to be used and the procedure to be followed. The theory underlying the particular experiment is also shown. Students prepare full records of all work done and are expected to develop logical conclusions. In the case of direct measurement, particular emphasis is laid on the errors of determination. The application of British Standard specifications is an important aspect of the lecture work. Copies of pertinent specifications, and other relevant publications, are available in the Laboratory, and students are urged to study them with reference to the apparatus being used. In conclusion, it is not suggested that the development of metrological studies in the College is now complete; on the contrary, it is hoped that future developments will allow the work to expand considerably.

Selection of the Genetic Basis for an Acquired Character

THE experimental results reported recently by Prof. C. H. Waddington[1] seem to make explicit in an important way what some zoologists, not professional geneticists, may have felt for long as something unsatisfying in many of the translations of evolutionary problems into Mendelian terms with which we are all familiar. He has reminded us once more that artificial selection, and so by presumption natural selection, acts upon animals having qualities, such as crossveinlessness, and not upon genes. He has shown that there are more genetic ways than one of being a crossveinless fruit-fly, and that, if crossveinlessness is selected for, then crossveinlessness will become established in a relation to the underlying genetic structure about which it is not clear that anything can in principle be predicted.

This most significant work seems to point once more to an element of insecurity in those approaches to the evolutionary problems of biology which by implication or statement rest upon the belief that these problems would be solved if we knew all about the distributions of genes in populations through time. Prof. Waddington has shown that again in his example the relation between the gene and the character is of just such a kind as will *not* enable us to say anything at all about genetic mutation-rates, or, indeed, genetic situations in any sense, in populations of which we know only the appearance through time. May it not also be true that this relation is of such a kind as will *not* enable us to say anything at all about the appearance through time of a population of which we know only the genetic make-up ? Have we not been forced to ascribe to the genes qualities and potentialities which impair the biological relevance of any knowledge of them to which we can in principle attain ? Part of the population of crossveinless flies at Edinburgh has changed the genetic basis of its crossveinlessness ; but could future workers, examining them dead, in principle know this ? A genetic situation at Edinburgh has become established by selection, in a relation (supposedly new) to crossveinlessness ; but could future population geneticists, seeking to calculate what must have been the frequencies of all genes in Edinburgh, have said anything about the way in which this would happen, or about the new relation which was to be established ? Possible future positions in a game of chess can be predicted from a given position, but only, in any practical sense, if the rules are kept. If a pawn can become a queen we must know what makes it a queen : for example, arrival at a certain place on the board. Procedural difficulties seem likely in making a prediction if what makes a pawn into a queen is its relation to other pieces *and* the necessity that white should win.

Much important recent work has given us a view of the widely differing rates of change through geological time in different groups of animals. Prof. Waddington has surely reinforced the impropriety of saying, and still more of implying, that this information is information about genetic change, whether by mutation, recombination, or of any other kind. We may not say that lampshells have low rates of genetic change ; we may only say that they look alike through long periods. Whether or not the success of a lampshell now is in any intelligible sense a consequence of the same genetic situation as made a lampshell similar to look at, and apparently equally successful, in different conditions a long time ago, is simply unknown, and now looks a little more unknowable. Perhaps Prof. Waddington has made us understand that to ask such a question is not sensible, and to answer it vain.

It may perhaps be urged that Prof. Waddington's example is exceptional, and that possibly argument from, for example, the homology of mutations, may show that, in general, characters are, have been, and will remain, 'due' to genes in a way that will justify translation of thought about populations into thought about genetics, and *vice versa*. But is this now, remembering again the warning of Harland[2], that "there are as many ways of making petal spot as there are species", more than a gratuitous judgement ? Does it even save the phenomena in a Ptolemaic sense ? Does it really save anything ? Does it not rather reduce the Mendelian concept to tinkling symbols in circumstances where they may not be the most appropriate ?

Recent Echo Sounder Studies

HODGSON[1] has shown that shoals of several species of fish give rise to traces on echo-sounders, and that a species may be identified by the shape of its trace. Echo-sounder records taken more recently by research vessels of this and other laboratories have shown that traces can be caused by an increasing variety of organisms covering a wide range of sizes, and that physical discontinuities in the water column are often associated with pronounced traces. For example, in August 1951 traces were obtained over a wide area off Whitby by the R.V. *Platessa*, using a Marconi sounder. They were found to be at a depth corresponding to that of a sharp thermocline, and small whiting about 3 in. in length, large medusæ, herring and *Ammodytes* larvæ were caught with a pelagic trawl at the depth of the trace. As the thermocline persisted outside the area in which the traces were recorded, the echo could not have been caused by the thermocline itself.

At about the same time, the R.V. *Ernest Holt*, working in the neighbourhood of Hope Island in the Barents Sea, found up to five simultaneous, relatively thin, horizontal traces in the upper 40 fathoms. These echoes persisted through other dense traces, which were associated with fish and other organisms ; their depths coincided with those of marked temperature gradients obtained on bathythermograph records ; and they exhibited oscillations due to internal waves. The traces were obtained on a Kelvin and Hughes *M.S.*24 30-kc. sounder using a 1,500-volt output and a 3-stage amplification, and on a Kelvin and Hughes *M.S.*21*b* 10-kc. sounder with a 2,000-volt output and a similar amplification. Similar traces were also recorded off southern Spitsbergen, where, as in the Hope Island area, relatively warm Atlantic

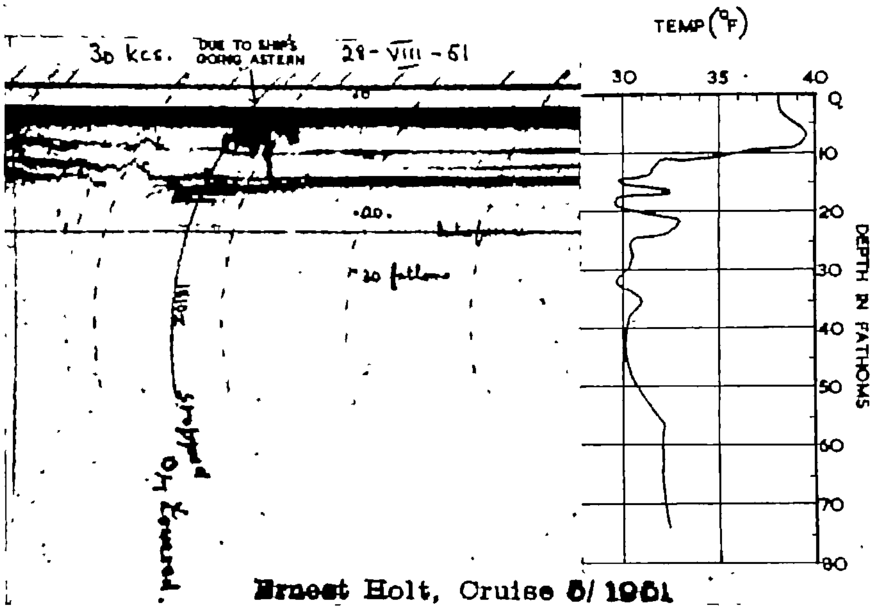

Fig. 1. Vertical temperature profile as recorded by the bathythermograph superimposed on the echo-sounder record

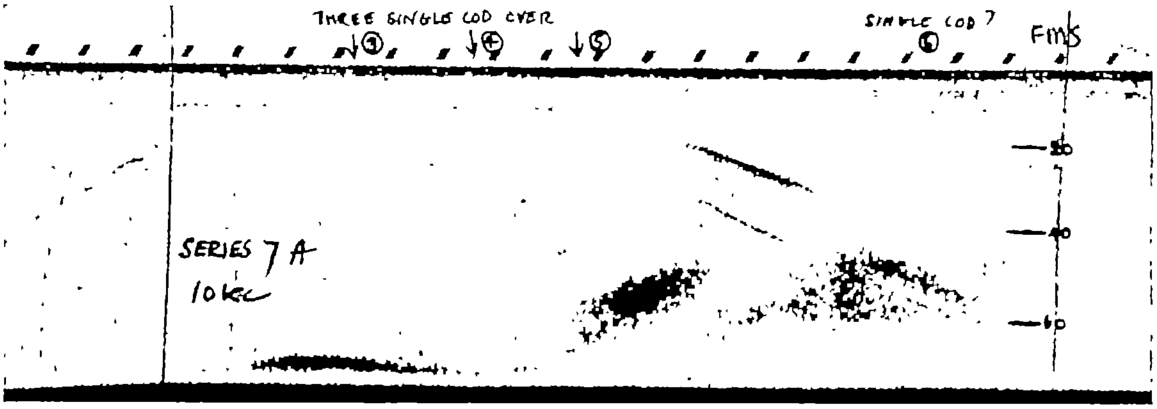

Fig. 2. 10-kc. Echo-sounder record from same cruise showing traces of individual cod, each of approximately 80 cm. length

water and cold Arctic water meet and give rise to a marked but complicated layering of the water. The nature of this hydrographical structure and the multiplicity of the traces suggest that the echoes could not have been caused entirely by planktonic organisms. Joseph[2] has shown, however, that sharply demarcated zones of high turbidity may exist in the sea. In the absence of more direct evidence, such factors cannot be excluded, and the traces cannot be attributed entirely to the structure of the water column. Further work is planned to determine the cause of these traces.

Hodgson and Richardson[3] have demonstrated the value of the echo-sounder as a means of studying shoal behaviour under varying stimuli. Traces obtained by the R.V. *Ernest Holt* suggest that sensitive echo-sounding equipment may also be used for studying the reactions of single fish. Single live cod of mean length 80 cm. were released from the lee rail and followed to 60 and 35 fathoms depth using full gain on the 10-kc. and 30-kc. sounders respectively. Similar depths were obtained using air-free cod, from which the air bladder and all tissue that might trap air had been removed. The sea was calm, but strong tidal streams were experienced; and it is not known whether the cessation of the traces at the depths stated above was due to the movement of the fish out of the sound cone or to the return signal strength of a single fish being below the threshold of sensitivity of the instruments. Comparisons between the depths to which cod could be recorded on each of the two frequencies cannot be made because of the different output of each machine.

Some of the live fish were seen to halt at the 'discontinuity trace' for a short time—one or two minutes—before continuing their descent. This reaction was not invariable and requires further investigation. It was observed when the temperature discontinuity was of the order of 3° C. in 10 ft.

Trematode Life-Cycle enacted in a London Pond

IT is well known that the larval trematode "*Diplostomum volvens* Nordmann, 1832" may cause impaired vision, and even blindness, in certain fishes. Rushton[1] and Baylis[2] have reported the presence of this diplostomulum in the eyes of rainbow trout in Britain. The presence of 20–40 parasites in the lens of each eye may favour completion of the life-cycle, because the fish then falls an easier prey to water birds. The definitive hosts of this trematode, *Diplostomum spathaceum* (Rudolphi, 1819), are various species of gulls, and the usual location is the intestines[3].

The eggs of this trematode hatch in water and the forthcoming miracidia penetrate water snails, generally *Limnæa stagnalis*, giving rise to colourless sporocysts from which the fork-tailed *Cercaria C* Szidat[4] emerge and promptly leave the snail. These pelagic larvæ float at various levels in the water in a highly characteristic posture; the furcal rami are divaricated and held uppermost, and the proximal region of the tail-stem is flexed so that the elongate body is held almost parallel with one of the rami. The cercariæ come in contact with fishes by chance, and after penetration they lodge in the eyes, getting into the lenses. Gulls obtain the trematode by devouring infected fishes.

I have recently observed that the entire life-cycle of *Diplostomum spathaceum* is being carried out in and on a very small, gravelly pond in London, not more than four miles from Charing Cross. The pond, often used for sailing model ships, contains much blanket-weed, decomposing leaves and other jetsam, and it accommodates various ducks and gulls. From it I obtained many large *Limnæa pereger*, most of which were heavily infected with trematode larvæ, double and triple infections being fairly common. The presence of dead and dying snails testifies to the intensity of the infections. By isolating living snails I have obtained daily several broods of cercariæ of stylet, fork-tailed and echinostome types. The fork-tailed larvæ were readily identified as *Cercaria C* Szidat, a study of which enables me to confirm most the behavioural characteristics outlined by Szidat[5] in Germany and Wesenberg-Lund[6] in Denmark. I have also noted the marked pathogenic effect of this cercaria on fishes.

Nearly every one of thirty three-spined sticklebacks more than 2 cm. long taken from this London pond had about twenty *Phyllodistomum folium* (v. Olfers, 1817) in the ureters and twenty to forty "*Diplostomum volvens*" in the lens of each eye. The re-infection of some of these fishes with *Cercaria C* revealed within a few hours both well-developed diplostomula and tailless cercariæ in the eyes. Such mixed infections as this illustrate the fact that the type of metacercaria which we call the diplostomulum undergoes considerable development in the fish host. The metacercariæ of a trematode such as *Fasciola hepatica* which encyst on herbage in the open do not develop further until they are taken in by the definitive host. At the other extreme, as it were, the metacercariæ of *Diplostomum spathaceum*, which are nourished at the expense of lens tissue, develop a completely transformed fore-body, which comes to have all the characters of the adult's body, and a rudimentary pouch-like hind-body which reaches full size in the final host only after the gonads have come to full development.

In my experiments, which will be reported fully elsewhere, I have determined that penetrating *Cercariæ C* kill minnows, goldfish, common carp, bitterling carp, tench, stone loach, perch and small sticklebacks overnight, and tadpoles within fifteen minutes. The fact that a few hundred cercariæ (which is only a fraction of the daily emission from one snail) will kill half a dozen fishes illustrates the intense pathogenic effect. From the eye of one minnow exposed for only a few hours to *Cercaria C* I have recovered nearly two hundred metacercariæ. The crucian carp seems to have greater powers of resistance than other fishes used in these experiments, but it cannot withstand three successive infections at two-day intervals. The nature of this severe pathogenicity is being investigated. One suggestion regarding the death of fishes is cerebral hæmorrhage caused by penetrating cercariæ.

Moonlight and the Pregnancy of Malayan Forest Rats

DURING the past four years, records have been kept of the state of pregnancy of a large number of rats and squirrels of various species collected and killed in connexion with scrub-typhus investigations. While studying the relation between rainfall and breeding season[1], it was found that the rates of pregnancy of the nocturnal forest rats showed a bi-monthly rhythm which appeared to be in phase with the moon, and which suggested that the greatest number of conceptions occurred near the time of full moon.

To investigate this further, the distribution of intra-uterine litters in the lunar month was calculated. Litters were classed as 'young' or 'old' according to whether the mean weight of the embryos was below or above the median of such weights for all litters of that species. There is some evidence[2] that, although intra-uterine mortality occurs, it affects individual embryos rather than whole litters; and if the loss of litters can be neglected, then the median (that is, the central) value for all litters will be the best estimate of the value at the mid-point of intra-uterine life. We do not know the gestation period for any of these animals, but by analogy with other members of the same family (white rat, black rat, white mouse, wood mouse, deer mouse, vole[3]) it is likely to be about twenty days, so we shall probably not be far wrong if we allow ten days for the life of a 'young' embryo and a further ten for the 'old'.

The dates on which the various litters were examined were then recalculated on a lunar calendar, as number of days from the new moon, and the results were grouped for the whole period for nearly four years. The result for one of the giant rats, *Rattus mülleri*, is shown in Table 1, grouped by five-day periods. There is, in fact, an excess of 'young' litters in the middle of the lunar month and excess of 'old' ones at the end; but the numbers involved are too small to eliminate the possibility of such differences

Table 1. Numbers of 'young' and 'old' litters of a forest giant rat, *Rattus mülleri*, by five-day periods of the lunar month (new moon = 1, full moon = *c.* 16) consolidated for the whole period April 1948–December 1951

Lunar dates	1–5	6–10	11–15	16–20	21–25	26–30
'Old'	2	1	1	0	4	4
'Young'	3	0	2	4	0	3
Total	5	1	3	4	4	7

Table 2. Same information as Table 1 consolidated for forest rats of the species *R. mulleri*, *R. sabanus*, *R. whiteheadi* and *R. rattus jalorensis*

Lunar dates	1–5	6–10	11–15	16–20	21–25	26–30
'Old'	10	10	8	8	15	21
'Young'	12	12	16	14	5	13
Total	22	22	24	22	20	34

$\chi^2 = 16 \cdot 7$. $P < 0 \cdot 01$.

being due to random variation. In Table 2, therefore, similar results for 144 specimens of the four most common species of rat from the forest, *R. mulleri*, *R. sabanus*, *R. whiteheadi* and *R. r. jalorensis*, are grouped. Since the classes 'old' and 'young' have been chosen to make them equal, and since sampling in the trapping register shows that the numbers examined in each period of the lunar month have been approximately equal, the number of litters expected in each box of the table is the same, namely, twelve. For the first two periods this is approximately true, for the next two there is an excess of 'young' litters, and for the last two a similar excess of 'old' litters. A χ^2-test gives a probability of less than 1 per cent that such differences are due to chance variations.

As a litter spends some ten days in the 'young' group, it is evident that there must be a burst of conceptions in the period immediately before the full moon, roughly coinciding with the sudden increase in effective moonlight which occurs at about the tenth of the lunar month.

That this phenomenon is likely to be a direct effect of the moonlight is shown by similar figures for the diurnal squirrels trapped in the same localities (Table 3). The numbers are rather smaller and have been grouped by ten-day periods; but it is clear that they do not differ significantly from the expected equality, whereas they do differ sharply from the figures which would be expected on the basis of Table 2. The probability that they differ from the proportions of Table 2 by chance variation alone is less than 2 per cent. Evidently the squirrels are not affected by moonlight, as would be expected of diurnal animals.

Table 3. The same information, but grouped by ten-day periods, for the common diurnal forest squirrels, *Callosciurus notatus*, *C. nigrovittatus* and *C. caniceps*

Lunar dates	1–10	11–20	21–30
'Old'	11	9	8
'Young'	11	7	10
Total	22	16	18

$\chi^2 = 1 \cdot 48$. $P = 0 \cdot 5$.

During the same period, 284 pregnant house rats (*R. r. diardii*) were examined (Table 4). Here there is the same tendency as with the forest rats, but to a much lower degree. The probability that the difference from equality is due to chance is between 5 per cent and 10 per cent, a level of significance below the conventional standard. This result agrees with the suggested effect of moonlight, since house rats are, presumably, exposed to it far less than are forest rats.

It seems probable, therefore, that in the nocturnal rats the onset of the period of bright moonlight near the time of full moon has some stimulating effect on conception. There are, no doubt, other examples of this or related phenomena which I have not heard about. I should be most interested to know of any other observations which may provide some explanation of the phenomenon.

Table 4. The same information, by five-day periods, for the house rat, *Rattus rattus diardii*, from the town of Kuala Lumpur

Lunar dates	1–5	6–10	11–15	16–20	21–25	26–30
'Old'	23	30	20	24	26	19
'Young'	26	23	32	20	19	22
Total	49	53	52	44	45	41

$\chi^2 = 10 \cdot 3$. $P = 0 \cdot 07$.

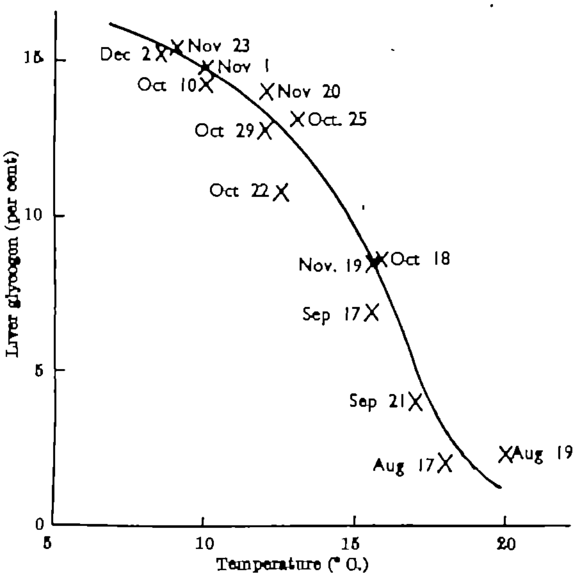
Environmental Temperature and the Glycogen Content of the Frog's Liver (*Rana temporaria*)

It has been generally concluded by previous workers that the glycogen content of the frog's liver in the autumn increases steadily as the season advances[1]. While this is probably true for the female, examination of the results for liver glycogen estimations made on fourteen samples which were caught between August and early December in 1948, 1949 and 1950, showed that this is not the case in the male frog.

Sometimes relatively low values were found in November and unexpectedly high concentrations in October. Some of these samples had been kept for three to five days in a tank-room at approximately atmospheric temperature, while others were actually killed in the field and the livers frozen in solid carbon dioxide for subsequent analysis in the laboratory. The temperature of the environment was recorded in each case, and it was found that when this was plotted against the mean glycogen content of the livers of the male frogs in the samples, the above-mentioned anomalies disappeared. This can be seen from the accompanying graph, where the observed points all lie reasonably close to a regular curve. Statistical analysis of the results shows a very significant correlation between glycogen content and temperature ($r = -0 \cdot 934$). From the graph it can be seen that the region of most rapid change lies between 12° and 17° C., as the slope of the curve decreases at lower temperatures. Glycogen attains its new level in the liver quite rapidly following a change of temperature. For example, on November 19, 1948, five male frogs were killed after being in captivity and unfed for three days. The temperature when this group was killed was 15·5° C. and the mean liver-glycogen content was $8 \cdot 5 \pm 0 \cdot 49$ per cent. On the following two days, when the average temperature had fallen to 10·5° C., six more males from the same sample gave a mean of $14 \cdot 4 \pm 0 \cdot 55$ per cent. Despite the small sample numbers, this difference is highly significant ($P < 0 \cdot 001$). The main temperature change occurred during the night of November 19, and the liver-glycogen content had reached its new level on the morning of November 20.

This relation between liver-glycogen content and temperature is apparently peculiar to the male and restricted to the period August to early December. In January, for example, a high glycogen content appears to be maintained despite a rise in temperature, unless precocious sexual activity supervenes, when the glycogen disappears quite rapidly even at low temperatures[1]. In the case of the female the amount of glycogen in the liver is low in August and September, and high in October, November and



Mean liver-glycogen content (percentage wet weight of liver) of male frogs, killed on the dates indicated, plotted against the temperature of the external environment

December, there being no obvious relation with the recorded temperatures. For example, in one September sample, the females contained 2·8 per cent liver glycogen at 15·5° C., while an October sample showed 9·5 per cent at 16·0° C. It would seem, therefore, that not only is the maximum glycogen content attained lower in the female[1], but also that it is not thermolabile.

It seems possible that the site of this action of temperature is at the level of the liver cells themselves, since adjustment of the liver-glycogen content takes place so rapidly. There may, however, be changes in the general endocrine system, perhaps of the type envisaged by Kepinov[2], occurring about the middle of August and December. A problem which still requires elucidation is the nature and source of the precursor of the not inconsiderable quantity of glycogen which appears in the livers of fasting male frogs without there being any regularly associated changes in the blood-sugar level. Experimental work on the action of temperature on glycogenolysis is at present in progress in this Department.

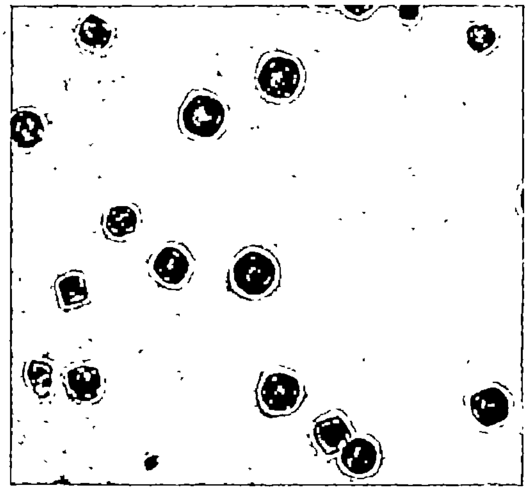
Presence of Ferritin in a Marine Elasmobranch, *Scyllium canicula*

FERRITIN has been isolated in the crystalline state from various organs of man, horse, pig, jackal, rat, mouse and guinea pig. On the other hand, the characteristic crystals have not been obtained from the tissues of the ox, sheep, deer and chicken. In the liver and spleen of the latter animals there is present some non-hæmin iron and some ferric iron bound to a protein component; but no crystals of ferritin are obtained with cadmium sulphate. Data on the distribution of this protein on the zoological scale are not complete; since it has an important function in the metabolism of iron, knowledge of its presence in other organisms would be very valuable.

We have observed in the liver of a marine elasmobranch, *Scyllium canicula*, the presence of a protein containing non-hæmin iron. The iron is present as ferric iron reducible to ferrous, like that of ferritin, with sodium dithionite. Applying the technique of Granick[1], we have obtained dark red crystals in the form of octahedrons, isotropic under the polarizing microscope.



The liver was homogenized in a Waring blendor with two parts of water (w/v) because of the high content of glycerides. The crystals show the characteristics and properties of those of ferritin. Apart from the liver, we have also obtained the same crystals from the intestine, although we have not succeeded in obtaining them from the spleen, perhaps because there is too small a quantity. The presence of ferritin in the liver and intestine of this elasmobranch suggests that the metabolism of iron in this animal is analogous to that in the animals listed above. Attempts to obtain crystals from the liver of teleostean fish have proved unsuccessful.

A New Species of the Mystacocaridea (Crustacea)

AMONG the numerous microscopic Crustacea brought back by the Lund University Expedition to Chile during 1948–49 was a new species of the sub-class Mystacocaridea, established by Pennak and Zinn[1] and recently discovered also in Europe by Chappuis, Remane and Delamare Deboutteville[2]. The species was obtained in the Pacific near the Island of Guafo in lat. 43° 33′ S., long. 74° 49′ W. on coarse sand in a depth of 25 m.

A comprehensive description of the new species, which belongs to the genus *Derocheilocaris* Pennak and Zinn, and its general anatomy, will appear in the reports of the expedition[3].

The head dorsally has what appears as a segmental border delimiting the part containing the protocerebrum (the so-called "rostral plate" of Pennak and Zinn) from the remainder of the cephalon. I consider this as a secondary development and not as a sign of a primitive segmentation of the acron (cf. refs. 4, 5). The antennæ, probably also the maxillulæ and the maxillæ, have a three-segmented protopodite, the mandible a two-segmented one. The occurrence in particular of two segments in the protopodite of the mandible—by far the most primitive found throughout the Crustacea—contradicts the opinion of Heegaard[6] that an unsegmented protopodite should be regarded as a primitive condition (cf. refs. 7, 8).

The nervous system is very primitive, although the peculiar position of the protocerebrum, deutocerebrum and tritocerebrum, which are widely separated, is probably due to the unusual shape of the acron. Anteriorly the acron is deeply cleft and each fronto-lateral projection carries two setæ, the nerve fibres of which can be traced to their entrance into the protocerebrum. On the lateral margins of the acron occurs one similar seta the nerve fibre of which can also be traced to the protocerebrum. The four anterior setæ are interpreted as probably representing the medial, originally unpaired, frontal organ, the nerve of which is always paired[9], the lateral ones as the paired (dorsal) frontal organ. There are generally two eyes of nauplius type at the base of each of the frontolateral projections, one situated more dorsally than the other. Probably the medial element of the nauplius eye has split into two which have gone one to each side together with the lateral element of the respective side. The splitting of the medial frontal organs and nauplius eyes is probably caused by the deep cleavage of the acron. The antennæ nerves come from the posterior part of the œsophageal commissure. The ganglion labrii is very large. Throughout the ventral nerve chain the longitudinal connectives are free. There is a free tritocerebral commissure and in each of the following segments a double free commissure is present. The ganglia touch in the medial line but without coalescing. The ventral chain is much more primitive than that of any other Crustacea excepting the Phyllopoda (for example, *Triops*) which it closely resembles.

The intestine resembles that of the Harpacticoida[10]. The stomodæum is very long and with a chitinous intima, the midgut begins in the hind part of the cephalothorax with an area with large, apparently secretory cells and is short and wide; the proctodæum occupies at least half the length of the abdomen. No cæca were observed.

The sexes are separate as in the European species[2]. In both sexes I have found the genital pore on the ventro-lateral side of the fourth segment (counting the maxilliped segment as 1), that is, I have seen the opening in the hypodermis but found no external pore. I have never seen more than one gonoduct and in three males and two females investigated it opens on the right side. The "yolk sac" of Pennak and Zinn, interpreted by Armstrong[11] as a spermatheca, undoubtedly represents a vitellarium. The yolk in immature females is formed by disintegration of cells probably from the posterior part of the ovarium. In mature females it is filled by eosinophile granules and surrounded by a membrane. The eggs, which are few and large, are obviously nourished by means of diffusion of dissolved substances. The testes are very large, occupying most of the dorsal part of the male thoraco-abdomen. Although there is only one ductus deferens, the testes are obviously of a paired origin and are provided with two longitudinal series of broad lobes. Sperm is produced in large quantities. There are no spermatophores. No copulatory organs have been observed.

With Pennak and Zinn[1] and against Armstrong[11], I maintain that *Derocheilocaris* cannot be referred to the Copepoda, but that a taxonomical group of the same order as the Copepoda must be created for it. The Entomostraca being ruled out as a natural group, the Mystacocaridea will obtain the status of a sub-class. From their nearest relatives, the Copepoda, they differ mainly in the greater primitiveness of the mouth parts, the location of the genital pore, the primitive structure of the genital organs and the nervous system. With regard to the latter organ systems, they approach the Phyllopoda or, rather, a generalized primitive Crustacean type. In several respects they are more advanced than the Phyllopoda.

Amino-acids in Legumes

In the course of analyses of vegetable foods with the view of evolving an entirely vegetable dietary which would be optimal in respect of protein, determinations of essential amino-acids were carried out on two legumes, Mysore dhal or lentil (*Lens esculenta*), and green gram or mung (*Phaseolus vulgaris*, Roxburgh). The determinations were carried out by microbiological assay. *Leuconostoc mesenteroides* and *Streptococcus fæcalis* were used with various media[1] in the assay of lysine, methionine, *iso*leucine and phenylalanine, and *Streptococcus fæcalis* in the assay of valine, leucine and threonine.

In view of current interest in the substitution of vegetable products for animal foods in nutrition[2], this preliminary communication may be of interest. Figures for *Phaseolus vulgaris* L. and soya bean calculated from published data are included for comparison.

Essential Amino-acids in Legumes
(Figures given are amino-acid nitrogen as percentage of total nitrogen)

Amino-acid	*P. vulgaris* L. (ref. 3)	Soya bean (ref. 4)	Lentil	Green gram
Lysine	7·2	7 9	7 9	8 7
Threonine	3·7	2 8	2·7	2 6
Methionine	0 4	0·8	0·4	0·7
*iso*Leucine	—	3·4	3·2	2·2
Leucine	8 8	5·1	4·6	5·2
Valine	4 0	4·0	4·1	4·8
Phenylalanine	2 9	2·7	2 6	2·7
Tryptophane	0·9	1 1	—	(1·1) (ref. 5)

Details of these investigations will be published elsewhere.

Serological Properties of Human Blood Group *A* and *B* Substances

During the course of the isolation and characterization of the human blood group *B* substance from some ovarian cyst fluids, it was observed that certain fractions of the mucoid materials obtained were relatively inactive in the usual iso-agglutination inhibition tests using naturally occurring β-agglutinin. The materials were, however, found to possess high activity when similarly assayed against human immune anti-*B* sera, which arose as a consequence of an incompatible transfusion or as a direct result of immunization with human group *B* substance or through an injection of horse serum. Rabbit immune anti-*B* sera which were produced by means of an artificial antigen made from human blood group *B* substance, and the serum of a chicken which contained a potent anti-*B* agglutinin after immunization with *Shigella shigae* and absorption with *O* and *A* cells, were also found to behave as did the human immune anti-*B* reagents. In these experiments, in which saline alone was used as diluting medium, all materials which inhibited the naturally occurring β-agglutinin also inhibited the immune anti-*B* sera.

The *B* substances in the *AB* materials isolated from three cyst fluids obtained from 'secretors' belonging to group A_1B behaved as did the selected mucoid materials mentioned above, and were found to possess negligible activity when tested with natural β-agglutinin but were highly active when tested against immune anti-*B* sera.

Materials with these restricted serological characters can be produced artificially from an essentially homogeneous human group *B*-substance (nitrogen, 5·8 per cent; fucose, 18 per cent; hexosamine, 20 per cent), which inhibits, at a dilution of 1 in 10^6, two to three completely agglutinating doses of either the natural β-agglutinin or the immune anti-*B* sera, by heating in an autoclave a 1 per cent solution of the purified *B*-substance in borate buffer (*p*H range 7·7–8·0) at 120° for about 45 min. Other weakly alkaline buffers within this *p*H range can also be employed. The *B* substance in fresh human saliva is similarly changed serologically after heating under these conditions.

The modification in serological properties of a group *B* substance which before treatment reacts with both natural and immune anti-*B* agglutinin is associated with a loss of viscosity and with the development of a capacity to give an 'N-acetylglucosamine' colour when treated with Ehrlich's reagent[1]. After heating under the conditions described, about 20 per cent of the material is found to diffuse through a 'Cellophane' membrane, and the diffusible material contains the whole of the chromogen and shows the changed serological character. The chromogen is not associated with the serological activity, however, since it is soluble in ethanol whereas the serologically active component of the diffusate is insoluble in this solvent. The indiffusible portion of the mucoid is found to possess a somewhat higher nitrogen and L-fucose content than the original material. Both the serologically active diffusible and indiffusible components react weakly or not at all with natural β-sera but show full activity when tested against immune anti-*B* agglutinin.

The serological specificities of human β- and rabbit anti-*B* sera have been studied in considerable detail[2], and it appears that human β-agglutinin contains two components, β_2 and β_3 and sometimes a third agglutinin designated β_1. Human group *B* erythrocytes contain receptors B_1, B_2 and B_3 corresponding to the three kinds of agglutinin, whereas rabbit red blood cells possess the specific receptors B_2 and B_3 only, and therefore in this species β_1 agglutinins alone can be formed. We have examined, by the methods of Friedenreich and With, some of our natural and immune human sera and have found that, regardless of whether or not our natural sera contain β_1, they are not inhibited by the selected mucoid materials or by the artificially modified *B* substance. The results suggest that the serological behaviour observed for the *B* substances is not related to the agglutinins β_1, β_2 and β_3 but is associated in some way with the normal or the immune character of the agglutinin. By postulating a further 'partial receptor' in the *B* specific complex, the antibody to which is found in human immune and animal immune sera only, our observations can be brought into line with the earlier views. This additional partial receptor is presumably more stable to the action of alkali than are the structures associated with the characters B_1, B_2 and B_3.

We have examined the activity of the two types of *B* material by means of the normal β-agglutinins obtained from persons belonging to groups A_1, A_2 and *O* and from an individual believed to be A_4. In one instance only, of twenty-one sera tested, did the anti-*B* agglutinin behave as an immune agglutinin, and it was afterwards found that the individual from whom this serum was obtained had received repeated injections of T.A.B., A.T.T., anti-typhus and anti-yellow fever vaccine. Thus it would appear that the differences in the heat of the antigen–antibody reaction reported by Wurmser, Armand and Wurmser[3], and believed by them to be related to the *ABO* genotype of the person producing the antibody, are apparently not associated with the differences in the reactivity of the natural and immune agglutinin described by us.

The examination of the behaviour of human *A* substance before and after treatment at *p*H 8 and 120° for different periods of time up to 45 min. revealed no definite differences in the behaviour of the materials with natural and immune anti-*A* agglutinins when A_1 cells were used in the inhibition test. After a longer period of heating, the *A* activity was considerably reduced or completely destroyed, and when the activity was destroyed for one anti-*A* serum it was destroyed for all the other sera examined. The replacement of A_1 cells in the test by A_2 cells, a procedure considered to increase the sensitivity of the test for the detection of *A* character[4], revealed that materials which possessed little or no activity when A_1 cells were used were fully active in the presence of A_2 cells. These results were obtained when both normal and immune anti-*A* agglutinins were used in the inhibition tests.

The *A* substance in the three active A_1B cyst fluids reported above appears to be of the type which shows low activity when examined in inhibition tests using A_1 test cells. Assayed against the same sera but using A_2 cells, the material showed considerable activity. Materials which possess a serological behaviour similar to that induced by heat treatment of fully active *A* substance can therefore be encountered in native cyst fluids[4].

These results indicate clearly the importance of examining serologically preparations of blood-group *B* substance or their partial degradation products, with both natural and immune group agglutinins, before concluding that the original serological specificity has been completely lost. Similarly, inhibition tests made to determine the activity of *A* preparations should employ A_2 as well as A_1 test cells. By these means important differences in the serological characters of preparations of the *A* and *B* substances can be revealed. The effect of different reagents, including enzymes, on the purified substances is being examined in greater detail in the light of these findings and will be reported elsewhere.

A Relationship between the Secretion of the Blood Group Antigens and the Presence of anti-*O* or anti-*H* in Human Serum

HUMAN and animal sera exist which agglutinate red blood cells of group *O* and A_2 more strongly than those of other groups; these have been known for many years as anti-*O* sera. In 1948 Morgan and Watkins[1] divided such sera into two kinds: those which could be inhibited by saliva from secretors of all A_1 A_2 *B* *O* groups, anti-*H*, and those which could not be inhibited, anti-*O*. Both types are found in human serum.

In this Unit it has been felt for some time that, apart from this clear distinction, the two types of antisera are indistinguishable in their reaction with red cells of the different *ABO* and *Lewis* groups. It occurred to me that one antibody (anti-*H*) if developed in a non-secretor person might be susceptible to inhibition *in vitro* by 'secretor' saliva, while the same antibody (anti-*O*) if developed in a secretor person might be immune to inhibition.

No information about the saliva of donors of anti-*O* and anti-*H* sera was available to test this possibility; there was, however, information about their *Lewis* groups, and these groups, as Grubb[2] and subsequent workers have shown, are closely correlated with secretion of the *A*, *B* and *H* antigens in the saliva. (All *Le*(*a*+) persons so far tested are non-secretors, and more than 98 per cent of *Le*(*a*−) people are secretors[3].)

Miss E. W. Ikin and Dr. A. E. Mourant very kindly provided fifteen samples of undifferentiated anti-*O* or anti-*H* sera, together with the *Lewis* groups of the donors. These sera, together with four others, were then classified by inhibition tests with saliva from secretor persons of group *O*. In each case, saliva from non-secretor persons of group *O* was used as a control. Details of two further examples of anti-*H* were kindly provided by Prof. Morgan[4]. The total count is:

		Red cells of donor	
		Le(*a*+)	*Le*(*a*−)
Antibody in serum of donor	anti-*H*	8	0
	anti-*O*	1	12

The probability that this lack of proportion is due to chance is 1 in 22,610.

Since 22 per cent of Europeans are *Le*(*a*+), the disturbance is mainly in the top row of the 2 × 2 table; from these results it would seem that when anti-*H* is made it is made by *Le*(*a*+) people.

Conversely, it may be that anti-*O* is usually made by *Le*(*a*−) persons, though the existence of the exception shows that this is not always so. The collection of sufficient data to show any significant disturbance in the second row of the 2 × 2 table may take a long time, for much larger numbers of donors of this rather rare serum, anti-*O*, will be needed.

It is difficult to imagine that the presence of the *Le*(*a*+) character on the red cells determines that the antibody in the serum is to be anti-*H*; the decisive factor is more likely to be the non-secretor environment in which the antibody is made.

Acetylcholine Esterase of the White Components of Blood

A PAPER by Zajicek and Datta[1] describing the presence of a high concentration of acetylcholine esterase or 'true' cholinesterase in the thrombocytes of rat blood recently came to my attention. I have known for some time that considerable 'true' cholinesterase is to be found in the white layer of centrifuged rat blood, and while I was working at the Medical Research Laboratories of the Defence Research Board, Ottawa, Canada, I showed by substrate and inhibitor studies that this is a typical 'true' cholinesterase. It was my opinion at that time that the enzyme was in the leucocytes rather than in the platelets; but in all other respects my work with rat blood confirmed the findings of the above authors.

After coming to England, I extended these observations to other species and found that the enzyme was present in very high concentration in the white layer of centrifuged mouse blood which consisted almost entirely of platelets, and in the same layer of cat blood; but I have not found any comparable activity in the white layer of the blood of man, or in that of the ox, sheep, pig, dog, rabbit or guinea pig. Species differences are characteristic not only of the true enzyme, but also of the 'pseudo' cholinesterase[2]. If the enzyme has any real function, it is difficult to understand what takes its place in the organs or cells of those species in which there appears to be no activity.

I am now making investigations to find out where the enzyme is localized in the active bloods, and if any function can be assigned to it.

I should like to acknowledge the help and encouragement of Dr. M. L. MacFarland, of the Defence Research Medical Laboratories, Ottawa, who supervised the research done in Canada, and of Prof. R. A. McCance, under whose direction the work is being continued in Cambridge.

Retinal Colour Processes caused by Intermittent White Light

It is a well-known fact that colour sensations can be produced by intermittent white light (the so-called subjective colour phenomenon of Fechner[1] and Benham[2]). This phenomenon has been investigated by us by means of a physiological method described in detail in a previous paper[3]. The electrical sensitivity of the dark-adapted eye was measured at varying intervals after exposure for 2 sec. of the central fovea to a pre-illuminating patch of 1° in visual angle. After removal of the light stimulus, the excitability recovers very rapidly, becomes supernormal and then decreases to the initial level. The maximum of supernormality lies at 1, 1·5, 2 and 3 sec. when red, yellow, green and blue lights are used for pre-illumination. The broken curves in Fig. 1 are examples of excitability curves for white light, which have a maximum at about 2 sec.

The curve for white light is increased in height and shifted to the right when yellow light is presented prior to the white light. Since this curve is similar in shape to that for blue light, the successive stimuli, yellow and white, may be taken as equivalent to a blue light stimulus. A group of such phenomena has been studied extensively in a previous paper[1] and termed 'retinal colour induction'.

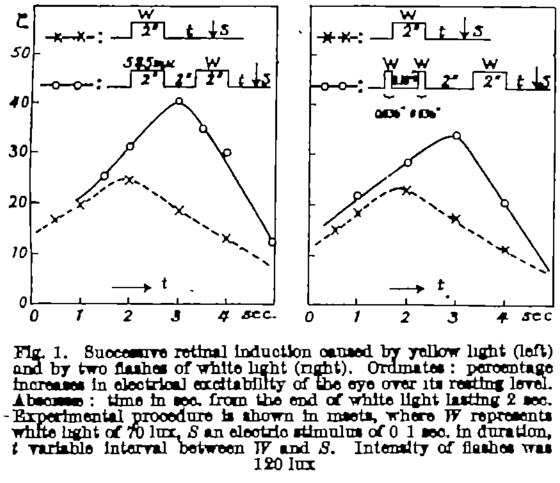

Fig. 1. Successive retinal induction caused by yellow light (left) and by two flashes of white light (right). Ordinates: percentage increases in electrical excitability of the eye over its resting level. Abscissae: time in sec. from the end of white light lasting 2 sec. Experimental procedure is shown in insets, where *W* represents white light of 70 lux, *S* an electric stimulus of 0·1 sec. in duration, *t* variable interval between *W* and *S*. Intensity of flashes was 120 lux

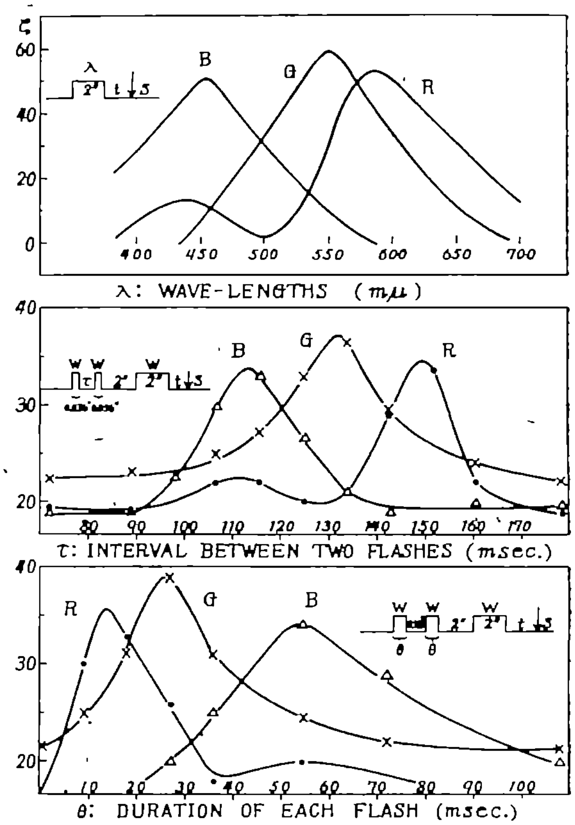

Fig. 2. Response curves for an equal-energy spectrum (upper diagram) and those for intermittent white light (middle and lower diagrams). Experimental procedure is shown in insets, in which τ and θ represent variable interval between two flashes of fixed duration 0·036 sec. and variable duration of flashes delivered at a fixed interval 0·125 sec. respectively

In the present investigation, it was found that two flashes of white light adequately spaced may be used as a substitute for the yellow light used in the experiment mentioned above. The curve obtained in this way is materially different from that for white light alone, showing a maximum at about 3 sec. just like a curve for blue light (Fig. 1). By varying the interval between two flashes, but under otherwise precisely the same experimental conditions, we succeeded in realizing effects of colour induction similar to those caused by spectral lights of various wave-lengths. In Fig. 2 it is demonstrated how this phenomenon depends on the interval between two flashes. For comparison, response curves for an equal-energy spectrum are illustrated in the upper diagram, in which data of electrical excitability at 1, 2 and 3 sec. after illumination are denoted by *R*, *G* and *B* respectively and plotted against the wave-lengths of pre-illuminating spectral lights. For reasons stated in the previous papers[3], the quantities *R*, *G* and *B* represent excitation of red, green and blue receptors respectively. It is to be noted that these response curves, determined by our physiological method, bear a striking resemblance to the fundamental sensation curves obtained by previous workers[4-7] from their colour-mixing experiments. The response curves shown in the middle diagram were obtained in the manner stated above, using two flashes of white light variously spaced and a subsequent white light stimulus of 2 sec. in duration. When the interval was shorter than 90 m.sec. or longer than 170 m.sec., the flashes showed no colour-inducing effect whatsoever, and the excitability curve was found to be the same as that for the white light alone. However, at intermediate intervals from 90 to 170 m.sec., very striking colour induction could be seen; as the interval was increased, the shape of the excitability curve, that is, the relative magnitudes of R, G and B, were systematically altered in such a manner that the induced colour changed from violet to red in the same order as in a spectrum (compare the upper and middle diagrams).

In another series of experiments the duration of flashes was varied, the interval between them being made 125 m.sec. The results are shown in the lower diagram of Fig. 2, which indicates that the induced colour changes from red to violet as the duration increases. Thus, an increase in duration of each flash acts just like a decrease in the interval. The ratios $R : G : B$ were found to change greatly upon varying the intensity of the flashes.

All these features of our physiological observations seem to reproduce well the properties of subjective colours, which are known to depend greatly upon the velocity of the rotating disk of Fechner or Benham and also upon the intensity of illumination. While the properties of the preceding flashes are obviously essential to the production of colours, alterations of the properties of the subsequent white light, such as its intensity, duration and temporal relation to the preceding flash produce no essential change in the results; colour effects can be seen even without the subsequent white light. It merely serves to turn colours caused by flashes into their complementaries.

Vitamin A Ester and Vitamin A Alcohol in the Serum of the Œstrogenized Immature Pullet

THE vitamin A of mammalian sera appears to be present principally as the alcohol, whereas the vitamin A of the liver is present mainly in ester form. As regards avian species, Neff *et al.*[1] have shown that the vitamin A of hen's egg yolk is present largely as the alcohol. Parrish *et al.*[2] have shown that the alcohol of the yolk is transformed in part to ester during incubation, and that the ester is the principal form in the livers of newly hatched chicks.

Administration of œstrogen greatly increases the level of vitamin A in the sera of immature pullets[3]. The state in which this extra vitamin A exists in the sera of œstrogenized pullets has now been examined. Sera have been collected from control and œstrogenized immature pullets in experiments undertaken for other purposes. These sera have been analysed for vitamin A by drying suitable samples by grinding with anhydrous sodium sulphate, extracting with petroleum ether and analysing the extract by the chromatographic technique of Narod and Verhagen[4].

The relevant results for two sets of observations are presented in Tables 1 and 2. The results for the control groups indicate rather low total vitamin A values, possibly due in part to comparative inefficiency of direct extraction with petroleum ether as compared with saponification and separation of the vitamin with the unsaponifiable.

Table 1. EFFECT OF ŒSTRADIOL BENZOATE ON SERUM VITAMIN A ALCOHOL AND SERUM VITAMIN A ESTER OF THE SEXUALLY IMMATURE PULLET (NEW HAMPSHIRE ♂ × BARRED PLYMOUTH ROCK ♀). AVERAGE RESULTS

Duration of experiment, 14 days. Hormones given by intramuscular route. Age of pullets at end of experiment, 74 days. All birds received same amount of food

Group	*E*	*F*
Number of pullets	5	5
Dosage œstradiol benzoate (mgm.)	nil	7 × 1·5
Dosage testosterone propionate (mgm.)	nil	7 × 1
Oviduct weight (gm.)	0·22	22·9
Serum vitamin A alcohol (μgm./100 ml.)*	3·3	2·6
Serum vitamin A ester (μgm./100 ml.)†	1·3	30·8
Serum vitamin A total (μgm./100 ml.)†	4·6	33·4

* Diff. not significant. † Diff. highly significant ($P < 0·01$)

Table 2. EFFECT OF GONADAL HORMONES ON SERUM VITAMIN A ALCOHOL AND VITAMIN A ESTER OF SEXUALLY IMMATURE PULLETS. (NEW HAMPSHIRE ♂ × BARRED PLYMOUTH ROCK ♀). AVERAGE RESULTS

Duration of experiment, 12 days. Hormones administered intramuscularly on alternate days. Age of pullets at end of experiment 89 days. All birds received same amount of food.

Group	*A*	*B*	*C*	*D*
Number of pullets	6	5	6	5
Dosage œstradiol benzoate (mgm.)	nil	nil	6 × 1	6 × 1
Dosage testosterone propionate (mgm.)	nil	6 × 1	nil	nil
Dosage progesterone (mgm.)	nil	nil	nil	6 × 1
Serum vitamin A alcohol (μgm./100 ml.)*	4·2	4·1	4·0	3·9
Serum vitamin A ester (μgm./100 ml.)†	0·9	2·2	42·8	47·5
Serum vitamin A total (μgm./100 ml.)†	5·1	6·3	46·8	51·4
Serum calcium (mgm./100 ml.)†	11·7	11·4	71·3	72·3

* Diff. between groups not significant.
† Diff. between groups *A* and *B* and between *C* and *D* not significant. Other differences highly significant ($P < 0·01$).

The results, however, provide fairly strong evidence for the conclusion that the increase in serum vitamin A of the immature pullet evoked by œstrogen is largely, if not entirely, an increase in vitamin A ester fraction. If the effect of œstrogen on serum vitamin A operates as a mechanism for the direct mobilization of hepatic vitamin A to the yolk, it would seem plausible to anticipate that œstrogen would enhance the level of the ester form rather than the level of the alcohol form.

It will be remarked from Table 2 that progesterone did not reduce the effect of the œstrogen on either serum vitamin A or serum calcium, although it depressed the hypertrophy of the oviduct evoked by œstrogen. Hertz *et al.*[5] have also remarked on the insignificant effect of progesterone on the response of serum calcium of the chick to œstrogen in experiments where progesterone reduced the effect of œstrogen on the oviduct.

Testosterone propionate by itself did not significantly affect serum vitamin A, a point which has already been noticed in this laboratory[6]. It is of interest to record, however, that testosterone propionate by itself may significantly increase serum carotenoids[6] although not affecting serum vitamin A.

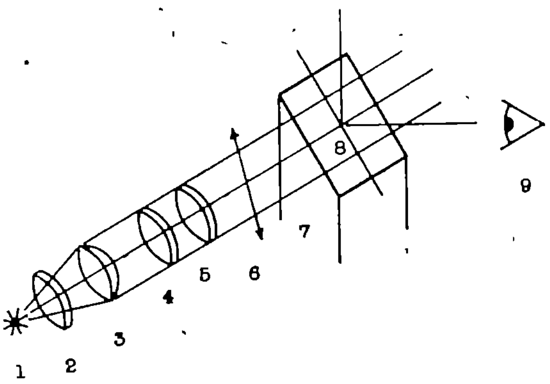

Fig. 1. Apparatus for the photo-elastic determination of surface stresses. 1, High-pressure mercury lamp; 2, heat-absorbing filter; 3, collimating lens; 4, green filter; 5, polarizer; 6, plane of polarization; 7, stressed model; 8, surface region; 9, observer

It is known that the components of a ray of polarized light traversing a stressed plastic model (of suitable material) will suffer relative retardations which are proportional to the maximum effective shear stresses in the path of the ray. These retardations may be seen in the form of interference fringes by viewing the ray through a second polarizer (analyser). Ordinarily, the analyser has been an element (Nicol prism, 'Polaroid', etc.) separate from the model, or use has been made of polarization due to scattering by particles within the model. In the present method for the determination of the stress at a point in the surface of the model, the surface itself is utilized as the analyser. To achieve this, the surface must be left in an as-machined condition, that is, unpolished.

A collimated beam of polarized light is projected through a section of the stressed model which includes the surface region under investigation. The model is aligned so that the tangent plane at the surface point is parallel to the direction of the beam. The plane of polarization of the beam should be adjusted to form an angle of 45° with the tangent plane. As the beam penetrates the model, the rays of the beam inside and adjacent to the surface will graze the tiny surface irregularities. Polarization by reflexion or refraction at these irregularities will result in the surface performing the function of the analyser. If the surface region is viewed from a position perpendicular to the direction of the beam and at an angle of 45° to the tangent plane of the surface point, an interference fringe pattern will be visible. The spacing of the fringes is inversely proportional to the effective shear stresses. It is possible to obtain the principal stresses by taking measurements for three orientations of the surface to the direction of the beam.

A simplified arrangement of the apparatus is shown in Fig. 1. It is usually necessary to immerse the model in a glass tank containing a clear liquid of the same refractive index as the plastic. This procedure reduces the refraction that would otherwise occur at the face of the model. To ensure that the surface fringe pattern will not be obscured by light scattered within the model, a material such as 'Catalin' with negligible scattering properties should be employed. As an illustration of a fringe pattern obtained by this method, a photograph of the tension surface of a beam in pure bending is shown (Fig. 2).

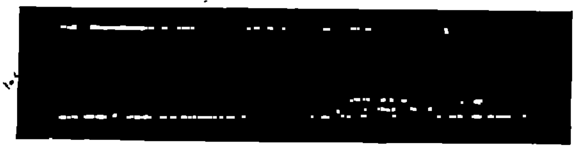

Fig. 2. Surface fringe photograph of the tension edge of a beam in pure bending

Several applications of this technique are now under investigation here.

Effect of Scopoletin on Indoleacetic Acid Metabolism

SCOPOLETIN is a normal constituent of many plants and is responsible for the blue fluorescence of oat roots[1]. An accumulation of this substance has been observed in tobacco[2] and potato[3,4] plants suffering from certain virus diseases, in topped tobacco[5] and in plants treated with 2,4-dichlorophenoxyacetic acid[6]. When applied to the growing tip of oat rootlets, it was found to be the most active of all the coumarin derivatives tested in causing inhibition of root growth[7]. Coumarin is believed to exert its effect by combining with sulphydryl enzymes concerned with growth[8].

In the presence of potato tissue, scopoletin is oxidized to a blue intermediary which turns yellow on standing. This reaction is inhibited by cyanide, azide, hydroxylamine and accelerated by hydrogen peroxide[3]. During the present work it was observed that the oxidation was also inhibited by diethyldithiocarbamate and manganous ions, but was not affected by carbon monoxide either in the light or dark. The pH optimum lay between pH 6·0 and 6·6. The properties of the scopoletin oxidase appeared to be so similar to those described[9-11] for indoleacetic acid oxidase that it seemed possible that the two were identical. In support of this concept, it was found that indoleacetic acid oxidase extracts prepared by the method of Galston *et al.*[9] actively destroyed scopoletin in the light (Fig. 1) and less actively in the dark. Scopoletin was determined fluorometrically. The colour changes brought about by indoleacetic acid oxidase extracts and scopoletin were identical with those obtained with potato tissue.

While indoleacetic acid did not inhibit the metabolism of scopoletin, scopoletin inhibited the destruction of indoleacetic acid by the oxidase (Fig. 1). The decrease in inhibition with time is attributed to the disappearance of scopoletin from the reaction mixture, since high concentrations or repeated small additions of scopoletin prolonged the period of inhibition. In the absence of the enzyme, scopoletin had no effect on indoleacetic acid, which was determined colorimetrically by the method of Tang and Bonner[10].

By applying the procedure of Lineweaver and Burk[11] to the results, it was found (Fig. 2) that scopoletin acts as a competitive inhibitor. It thus appears either that scopoletin is oxidized by a similar

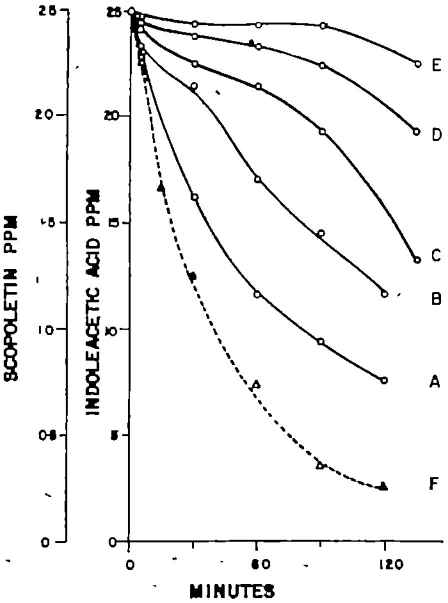

Fig. 1. Effect of scopoletin on destruction of indoleacetic acid by indoleacetic acid oxidase. *A*, no scopoletin; *B*, *C*, *D*, *E*, 2·5, 4, 12, 25 p.p.m. scopoletin respectively; *F*, scopoletin loss in reaction mixture containing 2·5 p.p.m. scopoletin

but different enzyme and competes for hydrogen peroxide, or that the two enzymes are identical and that scopoletin is preferentially attacked. Tang and Bonner[10] showed that *cis*- and *trans*-cinnamic acid and nine other analogues and auxin-like compounds had no appreciable action on the oxidase; we found coumarin also to be ineffective, so that it is not apparent why scopoletin, which is related to the cinnamic acids and to coumarin but not to indoleacetic acid, should show a competitive action.

If scopoletin behaves similarly *in vivo*, then it should simulate an auxin when applied to plants by its auxin-sparing action. It was found that the root-growth of peas soaked in 50 p.p.m. scopoletin prior to germination was temporarily retarded, while soaking in much weaker solutions (1 p.p.m.) resulted in a stimulation. This is analogous to the results of Thimann[13], who observed stimulation of root growth with low concentrations of auxin and inhibition with higher. Presumably with low concentrations of scopoletin, indoleacetic acid accumulates only within the stimulatory range, while with higher concentrations it accumulates in amounts sufficient to depress root growth.

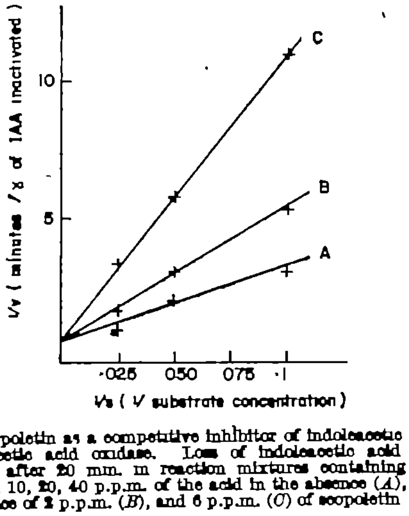

Fig. 2. Scopoletin as a competitive inhibitor of indoleacetic acid by indoleacetic acid oxidase. Loss of indoleacetic acid was determined after 20 min. in reaction mixtures containing the oxidase and 10, 20, 40 p.p.m. of the acid in the absence (*A*), and presence of 2 p.p.m. (*B*), and 6 p.p.m. (*C*) of scopoletin

Adsorption of Amino-acids on Sparingly Soluble Inorganic Solids

Among chromatographic adsorbents there is continually in progress a search for substances of higher adsorbing capacity and/or increased selectivity of adsorption. We have found that a number of sparingly soluble inorganic solids exhibit a small but definite binding affinity for amino-acids, and have attempted to relate such adsorption to certain physical properties of the adsorbent. The electrokinetic properties of both natural and artificial samples of several such solids have been investigated[1], and from these results it could be expected that such differences would be reflected in comparative affinities for binding amino-acids. Such has been found to be the case for the two amino-acids discussed here, namely, aspartic acid and glycine.

Solids of the type studied possess certain chromatographically desirable properties, such as low solubility and dimensional stability, which render column operation possible[2] in spite of the fact that their acid-combining capacity is low. The amino-acid adsorption by these solids was investigated by both column and static experiments. For the column experiments, 10 gm. of sample (− 52 + 72 B.S.S. mesh) was packed wet into a 7-mm. diameter glass tube. 200 ml. of the amino-acid solution containing 10 mgm. each of aspartic acid and glycine was allowed to percolate through the column at a flow-rate of approximately 1 ml. per min. The percolate was

Table 1. Column Adsorptions

Adsorbent	Amino-acid adsorbed (mgm. per gm. adsorbent)	
	Aspartic acid	Glycine
Natural zinc sulphide	0·41	0·24
,, lead sulphide	0·32	0·33
,, lead manganate	0·05	0 00
,, lead sulphate	0 20	0 34
,, barium sulphate	0·04	0·01
,, lead chromate	0·00	0·00
Fused lead chromate	0·00	0 00
Synthetic zeolite	0·72	0·25

collected and analysed for amino-acid content (Table 1) by a quantitative paper chromatography technique using the spot-area method[3]. For comparative purposes a column of a synthetic zeolite was prepared and used under identical conditions.

Since in any column operation there is a limited adsorption time, the relative adsorption-rates of aspartic acid and glycine for both natural and synthetic samples of the solids used in the column experiments were assessed by means of static experiments. In these experiments 1-gm. samples (– 200 B.S.S. mesh) were placed in 100 ml. of an amino-acid solution containing 5 mgm. of each of the above two acids. After intermittent shaking for an average period of six days, 25-ml. aliquots were removed and their amino-acid contents determined chromatographically (Table 2). A sample of synthetic barium chromate was used as an additional adsorbent.

Table 2. STATIC ADSORPTIONS

Adsorbent	Type	Amino-acid adsorbed (mgm. per gm. adsorbent)	
		Aspartic acid	Glycine
Zinc sulphide	Natural Synthetic	1·96 —*	1·80 0·44
Lead sulphide	Natural Synthetic	0·76 —*	0·61 0·12
Lead manganate	Natural Synthetic	0·84 0·08	0·64 0·00
Lead sulphate	Natural Synthetic	—* 0·28	—* 0·08
Barium sulphate	Natural Synthetic	—* 0·00	0·44 0·00
Lead chromate	Natural Synthetic Fused	0·60 0·40 0·84	0·52 0·00 0·40
Barium chromate	Synthetic	1·20	0·61
Zeolite	Synthetic	5·00	5·00

* Chromatographic irregularity of ninhydrin-developed spots prevented complete analysis of these aliquots.

From an inspection of Table 1 it can be seen that in all cases (except lead sulphate) the adsorption of aspartic acid was greater than or approximately equal to that of glycine. This observation has been confirmed by the results of the static experiments (Table 2), which show that the amounts of aspartic acid adsorbed on both natural and synthetic solids are decidedly greater than the corresponding amounts of adsorbed glycine. Table 2 also shows that in all available comparisons between natural and synthetic solids, the former exhibited higher adsorptive capacities for both amino-acids.

A study of the mechanism of the process of amino-acid adsorption on sparingly soluble inorganic solids and an attempted correlation between adsorptive capacity and the electrokinetic properties of the adsorbents have been made. An account of such results will be presented in a later publication.

Deposition of Metal Films on Jelly-like Materials

SUBSTANCES based on gelatine or agar-agar are used extensively for making moulds, from which replicas can then be made. In order to use the process of electroforming in conjunction with such jelly-moulds, it is necessary to provide the mould surface with a conductive layer. As agar composition, for example, contains about 95 per cent water, it is obvious that the moulds cannot be submitted to drying without causing deformation, and the usual method of coating moulds with aqueous colloidal graphite is therefore inapplicable.

Probably because of the high water-content of the jelly material, it was found to be impossible to produce films by silver-mirror techniques. The metallization by dry metal dust (for example, bronze powder) was rejected as not likely to yield sufficiently accurate reproduction. I have employed various impregnation techniques[1] which are now sufficiently improved to warrant trials in various fields of application.

The surface of the jelly is treated with aqueous silver-ammonio-nitrate made in the usual way. (Note: This preparation, which is widely used by dentists for impregnating natural teeth, is reported to be liable to become explosive. It is inadvisable to store large amounts, and the spent liquid should never be allowed to form crusts or to dry[2].) The liquid is completely evaporated by a jet of compressed air, but a sufficient amount of silver salt is left behind on the surface of the jelly. Instead of exposing this now to gaseous hydrogen sulphide (the resulting silver sulphide is brittle, unstable in acid solutions, and will not adhere to the jelly), the impregnated mould is exposed to *red* selenium, which is dissolved, for example, in carbon disulphide. Immersion in this solution for one to twenty minutes will produce a film of metallic appearance which probably consists of silver or silver selenide. It is transparent to light, conducts an electric current, but may float off when immersed in aqueous media. The film is obviously situated on the surface of the water-soluble silver salt, which was previously left by evaporation on the surface of the jelly. It is sufficiently stable to act as protection for the remainder of the salt, which can now be reduced to metallic silver, trapped as it is between the jelly and the silver selenium film. Suitable reducing media are some photographic developers, hypophosphorous acid (10 per cent), hydrazine-hydrate, etc., in which the treated mould will quickly be covered with a dense opaque film of high conductivity on which electrodeposition may be carried out. As an alternative, nascent hydrogen can be employed, which is evolved at the surface of the mould by making this the cathode in a cell containing acidified water. Apparently the conductivity of the initial silver (or silver selenium) layer is sufficient for this purpose, and soon the bulk of the silver salt is reduced to a dense metallic film.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT, Grade A (with a degree in chemistry, or A.R.I.C.) IN CHEMISTRY at the Coventry Technical College—The Director of Education, Council House, Coventry (July 19).

LECTURER IN CHEMISTRY in the Chemistry and Biology Department—The Registrar, Technical College, Sunderland (July 19).

RESEARCH ASSISTANT (with a degree in physiology, biochemistry or chemistry) IN CHEMICAL PATHOLOGY—The Secretary, Bristol Royal Infirmary, Bristol 2 (July 19).

RESEARCH OFFICER (male; a good honours degree in Science essential, together with a strong horticultural or agricultural background and some aptitude in mathematics or experience in the use of statistical methods) to maintain liaison between the Statistics Section and the N.A.A.S. Experimental Horticulture Stations and Provincial Experiments Committees undertaking experiments on fruit—The Secretary, East Malling Research Station, Maidstone, Kent (July 21).

EXPERIMENTAL PHYSICIST (with an honours degree in physics or its equivalent, and a particular interest in applied electronics) in the Physiology Department—The Secretary, Hannah Dairy Research Institute, Kirkhill, Ayr (July 25).

LECTURER IN AGRICULTURE (with special reference to poultry husbandry)—The Secretary, The University, Edinburgh (July 26).

LECTURER IN AGRICULTURE (with knowledge of farm mechanization, including field engineering and surveying and the principles of construction of farm buildings)—The Secretary, The University, Aberdeen (July 26).

SENIOR LECTURER or READER, and a DEMONSTRATOR, IN THE DEPARTMENT OF PHARMACOLOGY—The Registrar, The University, Leeds 2 (July 28).

ASSISTANT RESEARCH OFFICER/RESEARCH OFFICER IN THE SPECTROCHEMISTRY SECTION of the National Physical Laboratory, Pretoria—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, August 2).

EXPERIMENTAL OFFICERS at R.A.F. Signals Experimental Establishments in Bedfordshire and near London: SENIOR EXPERIMENTAL OFFICER (Ref. D.17/52A) for the development of calibration procedure for radio test equipment and preparation of calibration publications, etc.; an EXPERIMENTAL OFFICER (Ref. D.18/52A) and ASSISTANT EXPERIMENTAL OFFICERS (Ref. D.19/52A) for the calibration of transfer standards (*a*) involving frequency and pulse measurements, and maintenance of the frequency standard, (*b*) involving bridge and miscellaneous measurements, and (*c*) involving output and attenuation measurements—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting the appropriate Ref. No. (August 14).

ASSISTANT IN THE DEPARTMENT OF PSYCHOLOGY (qualifications in educational psychology are essential)—The Assistant Secretary of University Court, The University, Glasgow (August 15).

SENIOR LECTURER IN PHILOSOPHY at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

SENIOR RESEARCH OFFICER IN THE PROCESS DEVELOPMENT DIVISION of the National Chemical Research Laboratory, Pretoria—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2 (Pretoria, August 15).

SMUTS MEMORIAL FELLOWSHIP of Cape Town for research in botanical work on the South African flora, preferably in the systematics and geographical distribution of the South African flora—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (Cape Town, August 15).

PROFESSOR OF PHYSIOLOGY—The Registrar, South African Native College, P.O. Fort Hare, C.P., South Africa (August 31).

CHAIR OF PHYSICS at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 18).

POSTGRADUATE SCHOLARSHIP FOR TRAINING IN INDUSTRIAL RESEARCH—The Director, Institute for Industrial Research and Standards, Glasnevin House, Ballymun Road, Dublin (October 31).

ASSISTANT LECTURER IN CIVIL ENGINEERING, a READER or LECTURER IN MINING ENGINEERING, and a RESEARCH ASSISTANT IN THE DEPARTMENT OF MINING AND FUELS—The Registrar, The University, Nottingham.

BOTANIST (woman) in the Department of Agriculture, Tanganyika, for the selection, breeding and general improvement of crops, in particular food crops such as sorghums and maize, conducted mainly at the Ilonga Experiment Station, Kilosa—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. 27059/323.

CHEMIST in the Ministry of Supply at Chorley, Lancs, to control inspection of (*a*) propellants, powders, explosives, also filling and assembly of associated stores including Service ammunition, rocket charges, etc., (*b*) materials and components used in filler's components and for respirators, etc., (*c*) manufacture of ammunition packing cases including control of wood preservative, and (*d*) metal plating processes—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting F.463/52A.

EDUCATIONAL PSYCHOLOGIST (with honours degree in psychology; training in recognized Clinic and teaching experience essential) in Child Guidance Clinic—The Medical Officer of Health, Civic Centre, Southampton

ELECTRICAL ENGINEER to the Central Waterpower Irrigation and Navigation Commission, India—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting D 567/51-0-A).

GRADUATE IN CHEMISTRY, PHYSICS or ENGINEERING (for the speedy assessment and solution of current problems in industrial packaging the ability to write reports for the layman is essential)—The Printing, Packaging and Allied Trades Research Association, Randalls Road, Leatherhead, Surrey, quoting Ref. DPTO.

INVESTIGATORS (qualified metallurgists, chemists and physicists) to study various problems in the fabrication and use of non-ferrous materials—The Secretary, British Non-Ferrous Metals Research Association, 81–91 Euston Street, London, N.W.1.

LECTURER IN PHYSIOLOGY—The Secretary, Charing Cross Hospital Medical School, 62 Chandos Place, London, W.C.2.

LECTURER IN ZOOLOGY to teach up to B.Sc. degree standard—The Clerk, Northern Polytechnic, Holloway, London, N.7.

METEOROLOGICAL ASSISTANTS in the Falkland Islands Dependencies Survey, for service either at Port Stanley or in the Antarctic Dependencies—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.28185.E.

PHYSICIST at the Ministry of Supply Chemical Defence Experimental Establishment, Porton, Wilts, to undertake research work in connexion with the application of chemical formulations for the control of pests of public and animal health and agricultural importance—The Under-Secretary of State, Research Department, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

POLLUTION INSPECTOR (with a degree in chemistry and, preferably, with experience in the treatment of polluting liquids or in the control of pollution of surface waters) in Uganda—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. 27106/61/52.

PRINCIPAL—The Registrar, University College of Wales, Aberystwyth.

PRINCIPAL PHYSICIST by the Division of Atomic Energy (Production) Research and Development Branch, Culcheth, Warrington, to be responsible for the research work of a physics laboratory, applying physical methods to the study of metals, and to the development of methods of control of new metallurgical processes—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting Ref. 331.

SENIOR AGRICULTURAL CHEMIST, Jamaica, for general advisory and investigational work in agricultural chemistry—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. 27106/60.

SENIOR LECTURER IN TECHNICAL CHEMISTRY—The Secretary, Royal Technical College, George Street, Glasgow, C.1.

SOIL CHEMISTS (Ref. 'Soil Chemist 408'), PLANT BREEDERS (Ref. 'Plant Breeder 422'), and an AGRONOMIST (Ref. 'Agronomist 411'), in the Research Division of the Ministry of Agriculture, Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, quoting the appropriate Ref.

STAFF for experimental work in connexion with combustion and heat transfer in boilers—The Assistant Secretary, British Coal Utilization Research Association, Randalls Road, Leatherhead, Surrey, quoting Ref. A.15.

WELL SUPERINTENDENT (with at least 10 years experience in mining or well-sinking, and accustomed to the use of mechanical equipment and explosive) in the Public Works Department, Sudan—The Sudan Agent in London, Wellington House, Buckingham Gate, London, S.W.1, quoting "Well Superintendent 1814'.

HIGHER TECHNOLOGICAL EDUCATION

DURING the discussions on science and industry in the House of Lords on June 11 and 12, considerable attention was given to the proposal to build in Great Britain a technological institute of university standing. The speeches were noteworthy for their practical approach, and a most interesting feature was the change in emphasis on certain aspects. In view of the extent to which the scientific and academic world is divided on the issue of a technological university, the welcome which Lord Woolton's statement received in the House of Lords is impressive. Although he intimated that the Government has not decided exactly how the proposal is to be implemented, the importance of early action was uniformly stressed in the debate, as was the necessity of associating the new institution with the University Grants Committee and ensuring that it has the same freedom and independence as the universities themselves enjoy.

Lord Stamp's suggestion that the University Grants Committee is already too over-burdened to undertake such responsibilities, and that a parallel committee is required to cover technological education, did not imply dissent from this insistence on the academic independence of the new institution. He too, moreover, emphasized the distinction between higher technological education and technical education; indeed, a feature of the debate was the doubt expressed as to the possibility of technological and technical education being carried out in the same institutions, and the necessity for the production of technologists and technicians to be in balance. Lord Falmouth, for example, suggested that in some industries forty technicians are required for every high-grade technologist.

On such issues discussion is obviously handicapped until the Minister of Education makes the promised announcement of the Government's proposals for increased assistance for selected technical colleges and courses, and it appears from her answers to questions in the House of Commons on June 17 and 19 that this will not be forthcoming for a few weeks. From the second reply it appears that only the terms are then to be announced, and that it will be for the colleges themselves to apply for increased assistance. It does not follow from the wording of this reply that the selection is to be made by any one body responsible for the expansion of higher technological education as a whole, and for keeping it in balance with that of university education.

Misgivings as to whether the new proposals will result in the promised aid being spread too thinly over a large number of institutions, instead of being concentrated on four or five carefully selected having regard to national needs and resources, as was urged in this debate and elsewhere, are thus bound to persist at least until the Minister makes her statement. No doubt the observations made in this debate will be carefully noted by Lord Woolton and Lord Cherwell, who should be able to ensure that they receive due consideration when the Government makes its decision. Moreover, the debate should at least help to dispel any misgivings the universities themselves may entertain that the expansion of technological education is being conceived on narrow lines. The need for well-educated men and women was generally recognized, and there was a general agreement that technological education should develop in close association and in balance with the expansion of the universities themselves. Lord Wavell, indeed, frankly challenged the universities to strenuous thinking and perhaps adaptation of their constitutions to meet this need for maintaining a supply of scientific men able to sustain our wealth and influence in the world to-day and yet preserve all our old classical and liberal traditions of learning.

Due weight was given in this debate to the practical problems which attend the establishment of a new technological institution or the expansion of the technological departments of existing universities—the competition for staff and the availability of sufficient teaching staff of the highest calibre. The efficient use of costly equipment is another factor, as is the financing of research involving the use of such apparatus. It was appreciated, too, that the benefits of expansion accrue only slowly: Lord Hankey pointed out that although we have doubled the numbers of science graduates in the universities in five years, it will be some time before the increased numbers have their full effect.

The agreement in this debate on the importance of a wide and full education for the scientist and technologist was accompanied by a remarkable amount of support for the suggestion, which has frequently been made lately, that some reconsideration by the universities of the present distribution between science and arts faculties is required. It was argued in an article in *The Economist* of May 24 that a case appears to exist for some shift in the university population towards a greater emphasis on science and technology, at the expense of the arts. It is implicit in Sir John Cockcroft's article "Technology in the Universities" in the *Universities Quarterly* of May, in which he suggests that a further 50 per cent increase in the number of technological students is possible without upsetting the balance of the universities; Prof. R. S. Edwards reached a similar conclusion in a survey of the future of industrial research and development in Great Britain contributed to *Lloyds Bank Review* last January.

In the Lords debate, Lord Wavell in particular emphasized that by insisting on a broad training for scientific men, a programme involving a thirty per cent increase in graduates trained predominantly in science could be achieved with little or no disturbance of the balance of professors or extra laboratory space. The question is manifestly one calling for examination, and may well point the way to a solution of some of the difficulties to which the Advisory Council on Scientific Policy pointed in its recent report on man-power. It could scarcely fail to increase the supply of administrators with knowledge of science, and might also help to overcome the prejudices which at present appear to hinder some of the ablest talent in the schools turning towards a career in science. Similar views were expressed by Sir John Cockcroft in the *Universities Quarterly*. Welcoming the proposal for a new technological institution of university rank, Lord Waverley urged that it is also necessary to raise a few selected colleges of technology to university rank, and to detach them from the present system of technical education and place them under the University Grants Committee. The remaining technical colleges should be encouraged to develop their work in association with the great local industries. Sir John Cockcroft specified several colleges as suitable for development to university status, preferably in association with university departments, and he also advocated at least one really large college of technology, on the grounds that it would provide the needed increased facilities for post-graduate work. He also believed that the quality of university teaching in technology should be still further improved.

Sir John claimed that by these means the universities could make a further substantial contribution to technological education without increasing appreciably their total numbers. Besides more encouragement and funds for postgraduate research, an improvement in the numbers and status of professorial staff in some of the colleges of technology would be required; but the changes could be made at a cost which need be no more than a fraction of one per cent of our total expenditure on research and development.

Returning to the House of Lords debate, it undoubtedly reflected very fairly the trend of representative opinion on the question of technological education and its bearing on the future of Great Britain. Possibly the debate did not fully reflect the division of opinion in academic circles on one particular issue —that of the technological university—and only Lord Waverley appeared to raise the question of research at the development stage. Lord Falmouth, however, commented, as frankly as Prof. Edwards in the article referred to above, on the bearing of our present taxation policy on industrial research and development. The fact so generally recognized in the debate that the expansion and improvement of technological education in present circumstances must demand sacrifices elsewhere is the decisive reason for insisting that its development should be entrusted to some one body competent to handle it with due regard to that of the universities themselves, and of making the appropriate representations to ensure that technical education itself is kept in balance and enabled to supply the necessary numbers of technicians.

Nor is this a matter for the Government alone; whatever body, whether the University Grants Committee or the Advisory Council on Scientific Policy, is made responsible for handling it, will depend very largely on the co-operation of industry itself if the policy is to have full effect. It is not merely that, as Lord Chorley remarked in the debate, hostility to the university graduate still lingers in some sections of industry, and a major problem in reducing the discrepancy between the output per man in Britain and in the United States (which Mr. P. Hoffmann, formerly the Economic Co-operation Administrator, recently estimated as now two and a half times that of Western Europe) is to convey to the small firms generally a sense of the urgent need for a technological approach to the problems with which they are confronted. That, indeed, must be a first step before there can be any significant change in the situation in which, after allowing for the differences in the sizes of the labour forces and the population of the two countries, the United States are turning out and employing three times as many scientists and technologists as Great Britain. It should be taken while the plans for the expansion of technological education are being completed and put into operation, so that the demand is effective by the time the increased output of trained men is available.

The debate in the House of Lords gives a clear lead to the Government as to what is required and the urgency of the whole matter. Nor was the Government left in any doubt that the measures required will be costly, and that sacrifices will have to be made elsewhere in the national economy if anything effective is to be achieved. Success will not be attained by taking some of the £20 millions already allotted to the universities for the next quinquennium. On this point Lord Cherwell did not give the assurance for which Lord Falmouth had asked. None the less, the Government cannot fail to have noted the perspective in which the whole problem was placed in this debate, or the way in which it was urged that science and invention are unlikely to be harnessed as effectively as our international position demands while fiscal policy curbs so strongly pertinacity and initiative in industrial development. That the debate contributed little that is new does not make it any the less useful a stimulus to the constructive thought required on the part of Government, industry and the universities if an adequate policy for technological education and research is to be formulated and effectively implemented. The debate is also valuable for its contribution to the task of public education, which the Advisory Council on Scientific Policy has recommended as a prelude to the formation of a climate of opinion favourable to the effective utilization of science in industry.

THE AMERICAN GEOGRAPHICAL SOCIETY

Geography in the Making

The American Geographical Society, 1851–1951. By John Kirtland Wright. Pp. xxi+437+31 plates. (New York: American Geographical Society, 1952.) 5 dollars.

THE nineteenth century was a time of great voyages and striking discoveries in all parts of the world. Huge areas of Africa, Asia, America and most of the polar regions were unknown and were a lure to adventurers, prospectors, traders and colonists. The civilized world was eager for knowledge of remote and unfamiliar lands and seas. Both in Britain and the United States, wealthy men were willing to subsidize journeys that promised gain in trade and raw materials. Africa and the polar regions were special attractions to both sides of the Atlantic. The natural outcome was the grouping of these interests into geographical societies in both London and New York.

In its early days, the American Geographical Society was interested mainly in exploration, statistics and descriptions of new lands. Patrons were not wanting, and the Society grew in numbers and influence, and as quickly gave the impetus to American geography. It has had only some three directors in its life-time, and each has made marked impressions on its activities, especially the twenty years of Isaiah Bowman, who was appointed early in the First World War. Bowman tried to apply geographical thought to outstanding human problems. His was no narrow view of geography, and he was not concerned with defining and limiting its scope. One of his avowed aims was an intensified search for authors who would present geography in its diversity. He changed the *Bulletin*, the Society's publication, to the *Geographical Review*, broadened its scope and increased its originality, without reducing its value. In fact, it became one of the chief geographical publications of the day and did much to raise the value of the geographical outlook and the dignity of the subject. But Bowman did more. He started the preparation of research monographs covering a wide field, and, most ambitious of all, the Million Map of Latin America. This was in conformity with the International Million Map and covered 107 sheets. It took twenty-five years to compile the first edition, of which 61 sheets were published during Bowman's administration. The cost was close on half a million dollars.

The Society has no narrow outlook; it has adhered to a few simple leading principles, and has never accepted the doctrine that a sharp line should be drawn between geography and what is not geography, or that its interests should be confined within an academic definition of the subject. It may well claim to have raised the standard of achievement in geography in the past hundred years.

The book under notice, a heavy volume of nearly 500 pages, goes into details concerning the work of most of the officials connected with the Society. It is copiously documented, has a long list of publications and is illustrated by many portraits of officials and other geographers. It is a story of American geography as well as the life-history of the American Geographical Society [see also p. 98].

EXTENSIONS OF THERMODYNAMICS

Thermodynamics of Irreversible Processes

By Prof. S. R. de Groot. (Selected Topics in Modern Physics, 3.) Pp. xvi+242. (Amsterdam: North-Holland Publishing Co.; New York: Interscience Publishers, Inc., 1951.) 17.50 f.

THE laws of 'reversible' thermodynamics lead to relationships between the 'equilibrium' properties of substances, for example, specific heats, compressibility, coefficient of expansion, etc., such relationships following from the consideration that small disturbances of an assembly in equilibrium can, in principle, be regarded as reversible. These deductions can ultimately be justified by appeals to statistical mechanics—that is, they are consequences of the fact that a macroscopic assembly contains a very large number of atoms. It was long regarded as certain that similar relationships between transport coefficients, for example, heat conductivity, diffusivity, etc., could be found from general considerations, without the development of detailed theories for each effect.

This book discusses three distinct lines of approach to this question. Most of it is concerned with developing the consequences of the general results found by Onsager[1] in 1931, which are themselves consequences of 'microscopic reversibility' (sometimes referred to as the principle of detailed balancing). The fact that the equations of classical and quantum mechanics are symmetrical as between past and future time is shown to lead to general relations between the transport coefficients quite independent of their detailed mechanisms. Among many other results one can, in this way, give a proper derivation of Kelvin's thermoelectric relations, which, as Kelvin fully realized, cannot be deduced rigorously by the 'text-book' method of using reversible thermodynamics (because of the impossibility of finding conditions in which the irreversible effects associated with Joule heating and thermal conduction are both small).

Before the discovery of the Onsager relations, some progress in the theory of transport effects had been made along a somewhat different line. The idea was that entropy could be defined for an assembly 'not quite in equilibrium', the irreversible processes leading to a 'creation of entropy' at each point in the assembly, while the reversible processes implied a transfer of entropy from place to place. Such treatments were found to give satisfactory results for small temperature and pressure gradients, but it was not known how far they could be regarded as valid, as they must clearly break down for very large departures from equilibrium. Some indication of the limits of validity of such theories had become very desirable. For gases a quantitative answer has been found by Prigogine, by comparing the results of this 'extended thermodynamics' with those of the Chapman–Enskog kinetic theory—the conclusion being that the two theories agree as far as the second approximation of the latter theory, but that the expected breakdown of 'extended thermodynamics' occurs for cases where the third approximation is significant. The book should serve a useful purpose in directing attention to this interesting work, but a fuller discussion would have been welcome.

A third line of approach is the study of 'stationary states', typified by the flow of a gas through a nozzle or throttle-valve, the pressures and temperatures remaining steady at both ends. The text-book treatments of the Joule–Thomson effect and the 'wire-drawing' of steam illustrate how one can make quantitative deductions about such 'open' assemblies, again granted the possibility of defining entropy. The study of such 'open' assemblies is likely to be of very great importance in biological problems.

A typical biological process is the conversion of carbon dioxide and water into carbohydrates with the aid of sunlight. One may think of the living cells as being supplied steadily with raw material and energy, the products (for example, carbohydrates and oxygen) being carried away at an equivalent rate. Such an assembly is entirely different from the 'closed' assembly normally considered in classical thermodynamics, and it is only gradually coming to be realized that quantitative deductions about such an 'open' assembly can be made without detailed knowledge of the very complex chemical reactions which take place in it. It is a pity that the biological aspect of 'open' assemblies does not receive more attention in the book. (It gets less than a page.)

The book is very nicely printed and has only a very occasional error of spelling or grammar. The index, bibliography and list of symbols have obviously been prepared with very great care, though there is sometimes difficulty in tracing the reference relevant to a specific point in the text. The author implies that he found it impracticable to give 'foot-note' references. I feel that a disproportionate amount of space has been given to the Onsager relations, important though these are, and that more might have been devoted to the other two topics. In a future edition, it might also be worth including a discussion of the paradox that macroscopically irreversible effects do occur, even though the basic processes are microscopically reversible. This matter has been satisfactorily dealt with in a number of published papers, but the time seems ripe for dealing with it in a book.

This book is likely to remain a standard work of reference for some time to come.

H. N. V. TEMPERLEY

RECENT PROGRESS IN PHYSICS

Reports on Progress in Physics

Vol. 14 (1951). Pp. iv+412. (London: Physical Society, 1951.) 50*s*. net; to Fellows, 27*s*. 6*d*. net.

VOL. 14 of the "Reports on Progress in Physics" contains eleven articles, four of which deal with optics, three with nuclear physics, two with meteorology, one with microwave spectroscopy and one with the application of nuclear physics in medicine. The emphasis is on recent advances in the various subjects; but, as is customary in the "Reports", a mere listing of the subject-matter of recent research papers is carefully avoided. Each report is a model monograph, and enough background material is introduced to lead the reader by stages to an appreciation of the new advances or of the present established position of the particular branch of physics discussed.

In optics, a brief but important article by W. C. Price on recent advances in ultra-violet absorption spectroscopy deals with the development of new detectors, new sources and improved types of instrument, and, on the theoretical side, with the interpretation of ultra-violet spectra. Though the presence of an emission spectrum of the night sky has been known for a long time, it is only recently, and particularly since the end of the Second World War, with the introduction of improved instruments, that progress has been made in the investigation of the spectrum of the airglow and the aurora. This topic is the subject of a report by A. B. Meinel, of the Yerkes Observatory, University of Chicago. It is interesting to note that some progress has been made in assigning a height to each emission, a matter of some importance in the study of the physics of the upper atmosphere.

The optical properties of thin films, interference filters, the interferometric study of surface structures, Fabry–Perot étalons, interference refractometers and interference microscopes, form the main topics of discussion in the comprehensive report by H. Kuhn on new techniques in optical interferometry. The recent important advances and applications of this branch of physics, as exemplified by the work of Prof. S. Tolansky and others, need no emphasis; but Kuhn's survey, together with his references to new light sources and interferometric methods suitable for measurement of standards of length, is to be commended.

Finally, in this series of reports on optical phenomena, a historical survey of the diffraction theory of aberrations is given by E. Wolf, in which are traced the development of the subject from the early researches of Airy on an aberration-free image and the important advances made since 1940. This is the first article on the diffraction theory of aberrations to be published in the "Reports". However, as the theory is concerned with the study of images formed by actual optical instruments, it is of considerable practical, in addition to theoretical, importance and well merits a detailed report.

The selection of subjects to be included each year under the heading of nuclear physics must be very difficult, for the volume of literature on this branch of physics continues to be extremely large. For Vol. 14, angular correlations in nuclear reactions, nuclear interactions of cosmic rays, and nuclear effects in atomic spectra are chosen for individual reports. As in several other branches of physics, there is scarcely a problem in experimental nuclear physics the solution of which does not involve the measurement of an angle, and in his article on angular correlations M. Deutsch deals with the basic physical processes, experimental techniques and results of many experiments designed to study properties of nuclear energy states. The detailed and informative report which follows, by G. D. Rochester and W. G. V. Rosser on types of nuclear interaction, the properties of nuclear interacting particles and the correlation of nuclear events in the atmosphere and in condensed matter, is best summarized by quoting from the conclusion: "The general picture which emerges is one of rapid progress in the accumulation of empirical facts but little advance in our fundamental theoretical concepts. . . . Much remains then to be done, but the prospects are exciting. If the progress of the past few years can be maintained the coming years will see further rapid advances in this field of research and a solution of many of the problems which still baffle the nuclear physicist". The report by E. W. Foster on nuclear effects in atomic spectra is concerned mainly with results of optical investigations of hyperfine structure, particularly of isotope structure, and a description is given of recent work on the nuclear mass effect in helium. The subjects discussed are all receiving considerable attention by research workers at present, and it is interesting to read that the author considers that the appearance of improved experimental data and theoretical treatment is imminent.

The microphysics of clouds, by B. J. Mason and F. H. Ludlam, and a critical survey by N. C. Gerson of ionospheric temperatures are the two reports dealing with meteorology. In the first, microphysical processes—condensation, droplet growth, ice crystal formation, etc.—are mainly considered, and the results of recent experiments on the supercooling and freezing of water and on the behaviour of ice-forming nuclei are examined. The possibilities and limitations of methods of producing rain by artificial stimulation, a subject of general interest, are briefly discussed. The second report is a critical review of the relations which have been proposed between temperature and the various ionospheric parameters and of the methods for determining temperatures at altitudes of 100–400 km. The author concludes that there are considerable deficiencies in current knowledge, and meteorologists and physicists will be interested to read what these are and how they may be overcome.

The remaining two reports in Vol. 14 are perhaps the most appealing, one—anomalous fine structure of hydrogen and singly ionized helium, by W. E. Lamb—because it deals with microwave spectroscopy, a subject still in its infancy, and the other, some applications of nuclear physics in medicine, by W. V. Mayneord, because of its wider interest. In the former, not only is a clear and concise description given of the work, both experimental and theoretical, of Lamb, Rutherford and Skinner in which microwave methods are used to establish deviations from the Dirac theory of the fine structure, but also a brief review is made of the status of the theory prior to 1947 so that the non-specialist in this field may fully appreciate the problem that has to be tackled.

Vol. 14, like its immediate predecessor, is under the general supervision of the Papers Committee of the Physical Society, and the Committee, together with the executive editor, Dr. A. C. Stickland, are to be congratulated for the excellence of their publication. The criticism, made in the review of Vol. 13, of the absence of abstracts to reports does not now apply to Vol. 14, all the reports in which have useful contents lists and abstracts. S. Weintroub

PARASITISM AND SYMBIOSIS

Parasitism and Symbiosis

By Maurice Caullery. Translated by Dr. Averil M. Lysaght. (Textbooks of Animal Biology.) Pp. xii+340. (London: Sidgwick and Jackson, Ltd., 1952.) 35*s*. net.

THE second French edition of this book was reviewed in *Nature* (167, 495; 1951), and in that review the hope was expressed that it might be translated into English, a request for which had prompted Prof. M. Caullery to revise his book. The English edition is now available in the shape of this attractive and well-printed book, and the translator, Dr. Averil M. Lysaght, has done her work so well that everyone interested in this fascinating subject will be grateful to her for the care she has bestowed upon it.

The outstanding feature of the book is its synoptic, biological view of the two ways of life with which the work is chiefly concerned. The first three chapters deal with commensalism and with the transitions between this and inquinilism and parasitism. Seven chapters on parasitism follow, and the book concludes with three chapters on symbiosis. It is difficult to say which of these three sections is the most interesting. The author finds no natural distinction between commensalism, parasitism and symbiosis, and considers that these are "only categories created by us", which cannot, once they have been analysed, be delimited. "Under varied aspects they are only manifestations of the struggle for life." Those associations which have permitted the existence and perpetuation of the associated organisms have survived. Many other associations must have arisen, but have not been able to persist. The variety of structural and physiological changes shown by the successful associations are described in considerable detail, and many complex problems requiring further study by modern methods are indicated.

In parasitism these problems are numerous and intricate. This book leaves many of them out, because it purposely omits discussion of bacteriology and the important problems of immunity, which are discussed in other works. An adequate discussion of these aspects of parasitology would, indeed, have been impossible in a book of this size and would have defeated the author's admirable purposes. In symbiosis the problems requiring investigation are, in some respects, even more interesting. The pages of the book that deal with symbiotic organisms associated with insects—for example, with the possible part played by photogenic bacteria in the production of luminescence and with symbiosis among plants—provide fascinating material for extensions of research designed to settle the controversies discussed.

I have not noticed any misprints and only one important error has been noted, namely, the statement on p. 189 that the warble fly penetrates the host "under the same conditions as" the bot fly. This error dies hard. It has been clearly shown that the warble fly larva penetrates the skin of cattle and does not enter through the mouth, as do the larvæ of the bot fly.

A word about the bibliography is necessary. This, the author explains, is not meant to be comprehensive and, indeed, it could, in a book of this size, scarcely be so. The list of 598 references, to which the translator has added nine more, refers to work cited in the book, and this part of the bibliography is valuable. Two other brief sections of it, however, refer to general works and to special periodicals. Both refer chiefly to parasitology, and neither gives an adequate idea of modern parasitological literature. Of the nine general works cited, seven refer to parasites and, with one exception, they were all published in or before 1936. Of the meagre list of special periodicals, eight of the nine given deal with parasites, and many important parasitological journals are omitted. No one would expect a book of this kind to give a comprehensive list of works on parasitology, but, if any list at all is given, the reader is entitled to a modern and representative one.

The book is not, however, injured by this bibliographical fault. Its distinctive merit is its comparative study of parasitism, commensalism and symbiosis, and all students of these modes of life will read it with pleasure and profit.

G. Lapage

TEMPORARY REVERSAL ON BIFROST

The Bridge of Life

From Reality to Mystery. By Dr. Augusto Pi Suñer. Pp. vii+270. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1951.) 28*s*. 6*d*. net.

THE only bridge remotely resembling the one with which Dr. A. Pi Suñer is concerned, and like it mythical, is Bifrost. When last seen, the old Gods were moving steadily along it—out of the world and into Valhalla. This has led most men of science to assume that the process would continue and that the advance of knowledge would automatically restrict the area in which the gods could operate. We have preferred not to discuss whether Nature would ever be totally comprehensible, or indeed whether such a phrase can have any meaning, but have assumed that in our limited fields the gods were in retreat and materialist interpretations were extending.

This complacent attitude suffers jolts from time to time. There is a certain regularity in the process. As a new field of knowledge begins to be co-ordinated, some mystically minded pseudo-scientist thinks of a phenomenon in the middle distance and announces "You have explained so-and-so but you will never explain this". In this book the warnings are issued about instincts, consciousness and a curious mixture of life and time that obtrudes itself here and there. These are referred to as irreducible, and about them it is asserted that science cannot, and never will, tell us anything.

The best part of the book is a survey of various odd pieces of behaviour in animals and odd associations between them. This is interesting and lucid; but the choice of authorities is capricious. It is surprising to find Kipling's "Jungle Book" among them. The treatment of inheritance deals sympathetically with Lamarck and Lysenko; but on the basis of the rather dubious experimentation that held the stage in the 1930 period of this perennial wrangle rather than on the basis of more recent bacteriological evidence. There is some interesting backhanded Marxism in a section here in which the views of Cuvier and Linnæus are associated with their respective modes of acquiring titles. But much of this section is sketchy; it is a series of hints to the expert and confusions to the lay reader.

An examination of the borderland between two accepted and well-established disciplines—for example, between biology and chemistry—is always profitable if made by an expert, and even when it is made normally it is sometimes profitable. But an examination of all the borderlands at once needs more justification. *A priori* it is not likely that the same man could contribute usefully to each periphery. Experience with this book confirms the *a priori* judgment: not only does Dr. Pi Suñer meditate on most of the edges that exist, but he also considers some in which there seems to be little promise. There is, for example, a discussion about the biological significance of the probable use in the solar energy cycle of the biologically important elements hydrogen, carbon, nitrogen and oxygen.

It would be charitable to assume that some of the confusion is due to the translator, for the author has not been too well served by him. There are many infelicities of phrase and some scientific words are given wrong, or at any rate unusual, translations. But most of the fault lies with the author: he pays lip service to the scientific method and comments adversely on vitalism, metaphysics and "word-spinning"; but when the far side of his own medical speciality appears, we find as usual the ugly head of an ineluctible, irreducible god. Dr. Pi Suñer is not building a new bridge, he is simply repairing Bifrost and urging some of the gods to creep back. He may be successful in this, for irrationalism is now rife and books that encourage awe rather than curiosity spread it. We are given a medley of information and many quotations from the writings of the eminent; but the material is not arranged so as to bring out any clear principle. Instead, arbitrary assertions of inexplicability are made about some, at present unexplained, phenomena, and even these are not put very clearly. Such lack of clarity suggests that we may get warning of the return of the gods; the rout will be led by Loki, whose speciality was confusion.

N. W. Pirie

METHANE AND COAL*

By Sir ALFRED EGERTON, F.R.S.

COAL is the main stored source of the energy supplies of the world; every twenty years the world burns a volume of coal equivalent to the volume of Snowdon (a cone of base 8 km. by 1·1 km.). Coals were formed from ancient forests, mainly in the carboniferous era, about 250 million years ago, and the era lasted 30 million years or so. Some of the sources of coal are of later origin, and some is no doubt being formed now from decaying forests and swamps. Coals of all ranks—high and low rank—have a common generic relationship, as shown by the well-known curve of properties, such as the percentages of oxygen and of carbon falling within a fairly narrow band. In the main, coals are derived from the lignins and celluloses of plant debris and still retain some of the original structure of their vegetable origin. They are different chiefly because of the different pressure and temperature to which the material has been exposed; the higher-rank coals, in general, have been subject to higher tectonic pressure.

The Coal Survey has been providing a valuable examination of the coal deposits in Great Britain. Although there have been tremendous upheavals, displacements and folding of strata, the higher-rank coals have their origin in the central regions of the several coal-fields, and the coals of descending rank towards the periphery of the whole area or basin, in which coalification has occurred. Some ascribe this entirely to the effect of the pressure of the overburden, but, from investigations of German coal deposits, it appears that a fairly steep temperature-gradient may also be an important factor. Rock folding is consequent on great depths of sedimentary material, and high tectonic pressures and temperatures and disturbance of the seams result. There has also been modification by igneous intrusion in various regions.

It is dangerous to generalize on these matters; but it seems that study of the further coalification of low-rank material by submitting it to high pressure at various temperatures, carrying forward the work of Berl, Petrascheck, Bode and others, might give further information on what has occurred in past ages. The constitution of coals has been tackled mainly from the other direction—analytically, by looking at their structure or treating them with reagents. These methods, along with X-ray studies, seem to show that, in the bituminous range, coal has a structure of interleaved or randomly oriented layer planes of hexagonally arranged carbon atoms within which lies a still more jumbled, more complex structure with oxygen, sulphur and nitrogen atoms forming some of the links between the ordered carbon structure. These structures seem to provide sub-units of particles ten times larger (about 3×10^{-6} cm. diameter). This picture of coal, composed largely of colloidal particles, as suggested by the late Dr. Bangham of the British Coal Utilisation Research Association, with a very fine pore structure between the particles, fits reasonably with the pore size deduced from the density and from the measured internal accessible surface-area (about 100 sq. m./gm.) obtained both by heat of wetting with liquid methyl alcohol and by adsorption at 25° C. of the vapours of methyl alcohol, *n*-hexane, etc. The internal surface measured by adsorption of nitrogen at low temperatures (about − 200° C.) has given values about twenty times smaller, indicating that the pores are of larger average diameter and implying that the coals should be more porous to gases than they are found to be. The discrepancy between these two methods of measuring the internal surface is one of the most interesting results of recent research at the laboratories of the British Coal Utilisation Research Association and in South Africa and elsewhere, for with the clearing up of a discrepancy new knowledge is always obtained. (The porosity of coals depends, of course, on the nature of the coal and is not directly related to rank; there is in general a minimum for coals of about 89 per cent carbon.)

Dr. Ivon Graham has shown that a certain dried coal dust can absorb about twenty times its own volume of methane at 10 atmospheres; but he also showed that methane absorbed under pressure in a small block of coal is locked inside and can only leak out through the fine pores very slowly; with anthracites, even when finely crushed, the gas leaks out quite slowly from the fine particles. Graham endeavoured to measure the pressure of the methane locked in the pores of the samples of coal taken from the coal face, and the highest figure he got was a little more than 7 atmospheres. Lindsay Wood (1880) obtained the highest figure recorded (34 atmospheres) for the Bensham seam at 1,270 ft. At 1,000 ft. depth, however, earth pressures would still be about twice as great. Graham's measurements of the amount of gas liberated when small lumps of coal are finely crushed showed that 200–600 c.c. are released per 100 gm. for different samples, depending on the type of the coal. On the average, it would not be more than about ten times the volume of the coal—considerably less than 1 per cent by weight. This work tells something about the origin of firedamp. Some of it is gas from the pores of the coal when it is crushed in the process of mining, but probably the greater part is methane which has got locked up under pressure during the formation of the coal in breaks in the underground coal and rock structure, and is released when the coal is disturbed. Work has been done by Russian workers with the view of ascertaining how much methane could be stored in the coal substance at the high earth pressures at which coalification processes take place.

Where does the methane come from? The peat-forming stages of decay of vegetable debris involve aerobic disintegration by action of micro-organisms and fungi. The biochemical process may cease with only partial decomposition of the woody substances or may proceed to more complete digestion of the plant material, providing a jellified mass. The process sooner or later smothers itself and becomes anaerobic, and the product becomes consolidated and dehydrated' under its own burden. Gases such as methane and carbon dioxide can still escape; but before long they may become imprisoned by the overlying strata. From this stage down, biochemical reactions diminish; but the product is gradually further dehydrated, devolatilized and compacted, in fact coalified and matured under increasing pressure and temperature. (It is rash to mention a temperature; it is probably generally somewhere between 100° and 150° C. and only in exceptional circumstances rises higher than 200° C.) The degradation of the original plant celluloses and lignins in the production of bituminous coal would involve the removal of nearly twice the mass as gaseous products (methane and carbon dioxide) and water, and some have supposed that a quarter of the mass of the coal would have appeared as methane. The late Prof. Briggs and Prof. Hickling have written most interestingly on the subject. In the production of bituminous coal some suppose that dehydroxylation occurs and carbon dioxide and water are eliminated, but others are puzzled that methane as well as carbon dioxide is found. The anthracitization of bituminous coals, however, certainly seems to require the production of about 10 per cent of the mass of the coal as methane, as the carbon/hydrogen ratio has to increase and there is not enough oxygen to account for removal of hydrogen by water alone. Nevertheless, the amount of methane found associated with coal in mines is on the average only about 1 per cent of the mass of the coal.

---

* Based on the first Coal Science Lecture of the British Coal Utilisation Research Association, delivered on May 7 at the Royal Society.

What becomes of the rest of it? Leaving this rather intriguing question, to consider the occurrence of methane in the coal measures again. The pressure of the methane in the pores of the coal, supposing it were the only gas formed in the later stages of coalification at high pressure, would be at the pressure corresponding to the depth of the seam. There is, in fact, a tendency for higher gas emission in seams of high-rank coals and at greater depths. Dr. Ivon Graham's experiments showed, however, that the pressure of the methane in the coal is very much lower than corresponds to its depth, and very different in different coals; this is no doubt partly due to difficulties connected with getting true samples of the coal, but it is presumably mainly due to the gradual diffusion and escape of part of the gas. Furthermore, the coal is often removed (by geological displacement) to regions at much lower pressure than the depth at which it was formed. In some places where there are porous deposits above the coal, the gas can gradually diffuse out of the coal and soak away; in other places where this occurs, the gas collects in a porous region which is sealed by impervious rock and, if then a boring is made into this porous region or into faulting, the methane which has collected will be released under its own pressure. There are apparently not many coal areas in Britain where this occurs. The well-known Point of Ayr Colliery in Flintshire yields free gas (250–650 cu. ft./min., 98 per cent methane) at considerable pressure (up to 20 atmospheres); there are other 'blowers' in Staffordshire and elsewhere.

The many disasters from firedamp explosions in mines and the measurements of the limits of inflammability eventually led to legislation to keep ventilation of the mines well below the limiting concentration for danger. (Men are withdrawn if the concentration exceeds 2·5 per cent and electric current is cut off at 1·5 per cent.) On the average, about 6 tons of air is pumped through the galleries for every ton of coal mined and the methane in the out-going air is seldom as high as 1 per cent. If the average were even as low as 0·25 per cent, the recovery of the energy in the methane which is at present wasted would be equivalent to 3 or 4 million tons of coal a year, and it is well worth an effort to save as much of it as possible. There are two main possibilities, either to drain off the methane before it gets into the ventilation air, or to utilize the energy of the methane in the ventilation air, without trying to separate it. The first of these two possibilities has recently come into prominence.

Drainage of Methane at Coal Mines

As this 'drainage method' has been described fully in several recent reports and papers, only brief reference is necessary. In the Ruhr, the Saar and in Belgium, methane is now being drawn off by a system of bore-holes in suitable places. Several systems have been developed, the cross-measure hole method being most in favour. This method is being applied in about twelve British pits. The amount of methane drawn off appears to depend on the movement of the coal caused by the mining operations; disturbance of the coal causes disturbance elsewhere, increased permeability of the coal seam and flow of the methane along bedding planes to regions of lower pressure, and subsequent release into the galleries, unless caught on the way. The percentage of methane which is piped off from the boreholes is generally fairly high, up to 90 per cent of that which would otherwise find its way out. A drop of 50 per cent or better in the methane content of the ventilation air can therefore result. The old-established drainage system at the Point of Ayr Colliery is in a different category, for there the gas is stored at high pressures in faults, and it is essential to give it vent before working the coal. In Belgium, the mines are linked by pipelines, and a supply of 3½ million cu. ft. per day is maintained and is converted by cracking to a sulphur-free towns gas. In Germany, the gas is being compressed and used for motor transport. The object in view is increased safety in the mines, while obtaining a valuable product as a raw material for providing energy (power for the mines, or for heating of coke ovens, or as a raw product for other chemicals, synthesis gas, acetylene, etc.). Whether 'drainage' is worth while is very much a question of economics, setting the outgoings against the incomings, and each scheme has to be considered on its merits and in relation to local circumstances. According to report, it has been found that the value of the gas drained has generally more than paid for the installation and operating costs.

Utilization of the Energy of Firedamp in Ventilation Air

The main subject of this article is concerned with the second of the possibilities, namely, the direct utilization of the energy of the methane in the ventilation air. Dr. Roxbee Cox, chief scientist at the Ministry of Fuel and Power, has described in an admirable Hawksley Lecture to the Institution of Mechanical Engineers last year the projects which are in hand for the development of gas turbines for industrial purposes. One of the projects is one which has been suggested by C. H. Secord, of the Ministry:

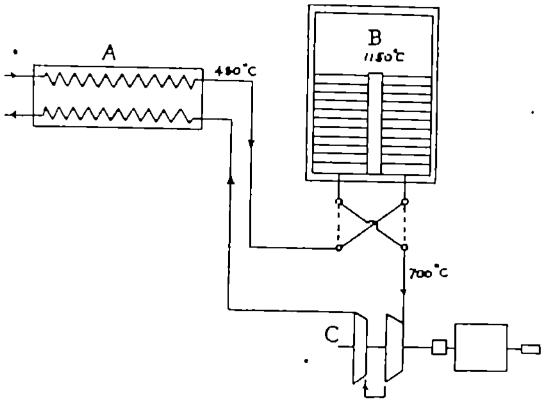

Fig. 1

if the waste methane in the ventilating upcast air from the coal mines could be burnt, the energy released could be converted by a gas turbine into sufficient useful work to provide a large part of the power needed in the collieries. Can such a small proportion of methane (about 0·5 per cent) be burnt ? Knowing that methane can be oxidized well below the limiting mixture strength needed for flame, the suggestion seemed to me worth pursuing, and a few preliminary experiments were made (early in 1949) which showed that fairly rapid combustion could be got in the region of 700–900° C. R. G. Voysey, a member of Dr. Roxbee Cox's staff, thereupon produced a scheme, and Fig. 1 shows the general principle : *A* is a preheater exchanging heat between ingoing and outgoing gases, *B* is a regenerator-exchanger or 'booster', in which the gases are maintained at the temperature necessary for reaction, and *C* is the turbine.

If the temperature rise caused by the combustion of about 1 per cent of methane is 250° C., and 900° C. is the temperature to which it has to be raised for rapid ignition, then, supposing that it enters at 450° C., it will have to pick up 450° C. from the booster, the temperature will rise to 1,150° C. on ignition, and after giving up heat to the other leg of the booster it will drop 450° C. and go to the turbine at 700° C. The valves of the booster are changed over at appropriate intervals to keep the process going. It is very necessary that the combustion should be rapid, otherwise the exchanger booster will be large and costly.

The booster, largely designed by P. D. Edmundson, of the Ministry of Fuel and Power, and constructed by the Incandescent Heat Co., has already undergone successful trials. The engineers, in designing the booster, needed to know how the methane would burn in it. The velocity of the air stream would be about 200 ft./sec. (65 m./sec.), and the residence time in the hot zone might therefore be only a few milliseconds. At what temperature would the combustion start in such circumstances ? Would it be completed quickly when started ? Could it be burnt at a lower temperature by addition of special vapours or by change of surface conditions ? How would the combustion be influenced by other combustibles ? These were some of the questions investigated by A. D. Meads and later by H. Hirsch, under Dr. J. H. Burgoyne's supervision, in the laboratory of the Department of Chemical Engineering and Applied Chemistry of the Imperial College of Science and Technology, London.

Investigation of the Combustion of Weak Mixtures of Methane and Air

It was decided to fix on a rate of flow (0·126 cu. ft./min. at 20° C.) and size of refractory tube ('Mullite' 3/16 in. internal diameter) which would correspond approximately with the expected flow-rates and surface/volume ratio assumed for the preliminary design of the booster matrix. The effect of change of composition and of pressure on the temperature for rapid combustion and on the duration of the reaction was studied. The methane and air could either be preheated separately or after mixing. It was established in the preliminary work that the reaction was taking place homogeneously in the gas phase, starting not at the surface but between the boundary layer and the fast-moving core, and that the mixing of the two separate streams was very rapid and occurred well within 1 cm. of admission (0·4 m.sec.). Most of the work thereafter has been done by heating the methane and air separately, and bringing them directly into the reaction space.

The 'Mullite' tube was about 1 m. long ; the length of the reaction space (less than 10 cm.) could be changed by pushing in the closely fitting exit tube. The furnace was specially contrived to provide even heating, and the temperatures were measured by a suction pyrometer in an identical tube alongside, through which passed the same flow of air without methane. The changes of percentage of methane and of carbon monoxide have been measured by infra-red analysers, which have made it possible to study these fast reactions. The following figures show the temperatures which are needed to cause 95 per cent combustion of a 1 per cent methane/air mixture :

Length of reaction space	Residence time at inlet after mixing	Temperature of gases at inlet
6·5 cm.	3·8 m sec.	1,020° C
4·5	2·4	1,041
1·5	0·3	1,076

All the temperatures referred to are the temperatures of the preheated gases entering the reaction space (and therefore no correction is needed for rise in temperature due to reaction). In 4·5 cm. only 10 per cent is burnt at 1,020° C., so that in the next 2 cm. the combustion, when once started, is all over in about 1 m.sec. There is a delay of nearly 2¼ m.sec. before any appreciable reaction happens. This is fundamentally interesting, in relation to some other experiments on flame propagation. In a flame, gases are heated to the temperature at which they inflame. In these experiments they are preheated until they react rapidly, and that is just what is happening in a flame front.

If gases are passed through a burner in which the gas stream is divided into a number of small channels, in each of which there is stream-line flow on emergence, the streams have a velocity distribution which is the same across the burner. One gets a flat flame[1]. In order to maintain the flame, the gases must be heated up to the temperature of inflammation (that is, the temperature of the lower boundary of the surface of the flame), which for a weak methane/air mixture is about 1,200° C. The distance in which the heating can occur is about 0·03 cm., because at that distance from the flame-front the gases are still too cold to react rapidly. They are moving at about 6 cm./sec. (at 20° C.), so they have less than 2 m.sec. in which to react and reach a temperature of 1,200° C. If when they are already at 1,000° C. according to the 'Mullite' tube experiments, they seem to need 2–3 m.sec. to ignite, it scarcely seems likely that the time available in the flat flame would be sufficient to inflame the gas at the flame boundary. In making that statement, it is assumed that the gases depend for their ignition on heat generated by pre-reactions set up by heat conducted from the flame. It is therefore believed that something else is happening in the gases before they reach the flame front. It is thought these experiments support the view that radicals (probably hydrogen atoms) streaming back from the flame, besides the heat of the flame, are necessary to start the reactions and maintain a flame in existence. Experiments carried out by B. C. Mullins at the laboratories of the National Gas Turbine Establishment on ignition of methane in fast streams of gas indicate even longer ignition-delays at 1,000° C. than those obtained at the Imperial College. I have mentioned this offshoot of the work because it illustrates how study of a technical problem can lead to results of importance in purely academic studies, in this case on the problem: How does a flame maintain itself?

To return to the oxidation of methane, it has been found at the Imperial College that: (1) the effect of pressure up to $2\frac{1}{2}$ atmospheres only slightly decreases the temperature of combustion; but oxygen enrichment decreases it quite considerably; (2) the weaker the mixture (down to 0·5 per cent), the lower the temperature for rapid combustion; methane therefore appears to inhibit its own ignition at these high temperatures; (3) that 0·125 per cent of hydrocarbons and hydrogen lower the ignition temperature quite appreciably but only in proportion to their contribution to the total heat content of the mixture in burning to carbon monoxide.

Does the methane burn at once completely? It was important to know the answer to this question, for, if it is only partly burnt, the full available energy cannot be converted in the turbine. With constant residence time (4–5 m.sec.), the 1 per cent methane burns more and more completely as the temperature rises, until at 1,020° C. it has been completely burnt. Carbon monoxide is formed by the combustion of the methane; its combustion is inhibited by the methane, and it only begins to burn after practically all the methane is burnt. The carbon monoxide, however, does not burn completely in the time available unless the temperature is raised to 1,050° C. These results show that the combustion of methane is not a single but a dual process, being composed of two separate processes of different rate: the combustion to carbon monoxide; and the subsequent combustion of the carbon monoxide, the second being inhibited by the first. Fig. 2 shows how marked is this effect. 1 per cent of carbon monoxide (moist) would burn rapidly at 777° C., but with 1 per cent methane it will not burn until the temperature is raised a further 200°, and then only when the methane has been burnt. It is obvious there is some radical essential to the combustion of carbon monoxide which is destroyed by a hydrocarbon, like methane.

This effect has been noted by others in mixtures of much higher concentration in the region of ignition limits at lower temperatures. During the Second World War, the flaming of exhaust from aircraft at night had to be reduced. It was found that hydrocarbons (lubricating oil, for example) injected into the exhaust helped to prevent the blue glow due to combustion of residual carbon monoxide when the hot exhaust-gas discharges into the air. R. R. Baldwin[2] has shown that the combustion of hydrogen, as well as carbon monoxide (moist), is inhibited by hydrocarbons to an extent dependent on the oxygen concentration. He has suggested that the hydrocarbon removes hydrogen atoms, since these alone react with oxygen in the hydrogen–oxygen reaction. He assumes that these hydrogen atoms react with hydrocarbon and give rise to a hydrocarbon radical, which is afterwards destroyed. This explanation, however, does not seem to fit with the self-inhibition of the oxidation of methane.

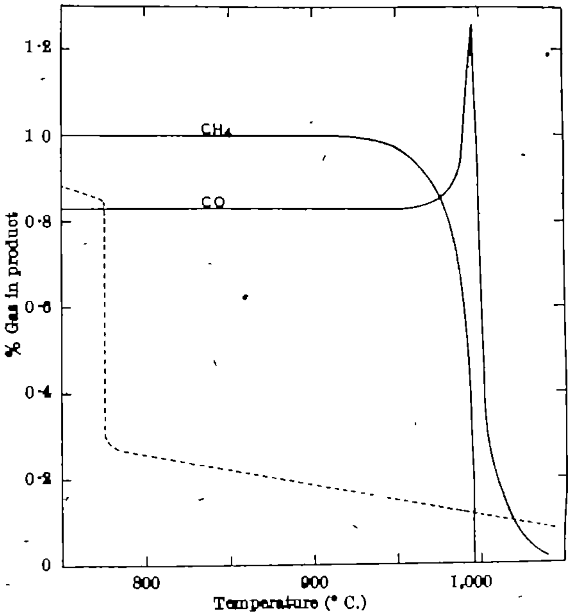

Fig. 2

It is not at all certain yet what is precisely happening in any kinetic gas reaction; even in the case of hydrogen and oxygen, new phenomena turn up which have to be accounted for by new suppositions. D. R. Warren has suggested that ozone is the only likely common constituent of all oxidation reactions, and yet his own discovery of the effect of boric acid on the second ignition limit of hydrogen–oxygen seems to rule out at once any explanation of the hydrogen–oxygen reaction in terms of ozone as a chain carrier. Nevertheless, the dry carbon monoxide reaction seems to demand ozone as a chain carrier, and it is interesting that in these methane weak-mixture reactions ozone is certainly formed at an early stage. These experiments on the oxidation of weak mixtures of methane have yet to yield their full fruit. In this connexion, G. J. Minkoff and A. J. Everett have found that, in spark-ignited mixtures of methane and oxygen cooled in liquid air at low pressures, the flame is remarkably rapid and is attended by a glow lasting several milliseconds, and that considerable amounts of ozone and hydrogen peroxide are chilled out on to the walls of the tube; methyl hydrogen peroxide is also detected, but no formaldehyde. These various lines of work are converging to provide quite considerable information about these rapid chain reactions which control the propagation of flames.

There are now two ways open for the utilization of the mines gas—either by drainage, or by the direct combustion of the methane in the ventilating air. Which is the better way will depend on local circumstances and many other different considerations. They are not mutually incompatible. The drainage method only removes part of the methane that would otherwise find its way into the ventilating air. If, for safety reasons, methane drainage were necessary, it might still be thought worth while, instead of burning the methane under boilers or in diesel engines, to burn it in a combustion chamber along with the ventilating air containing the rest of the methane and gain the power by gas turbine. But having separated methane at high percentage, it seems a pity to burn it; it should be used so as to obtain its value as a high-grade fuel.

Methane as a Fuel for Internal-Combustion Engines

Methane is an excellent fuel for spark-ignition engines. M. Pearce had shown that the same engine on methane with spark ignition at 14 : 1 compression ratio gave 34 per cent more power than when running as a diesel engine on oil. This is because of the high knock-rating (highest useful compression ratio 16 : 1) of methane. N. P. W. Moore and W. T. Lyn have been studying the behaviour of methane in a motor engine at high pressure and have shown that a pale-blue flame precedes at a somewhat lower pressure the white flame of the true ignition. Again, this is perhaps evidence of the dual nature of the combustion.

Attention is directed to the behaviour of methane in engines not only because of its special interest in relation to the problems of combustion, not only to show again how all these different aspects of the combustion of methane interconnect, but also to suggest that its special value as a fuel for internal-combustion engines should not be neglected. Methane obtained by the drainage method in the Ruhr district is being compressed and utilized for motor transport, and this may well be one of the most profitable ways of using it, rather than using it for heating coke ovens or passing it into gas mains after suitable reforming.

Liquid Methane

For many years we have been interested in the possibilities of methane in the liquid state (b.p. − 161° C.). The late Lord Cadman directed my attention to the enormous volumes of methane which went to waste in the Persian oil-fields. I suggested at the time that it might be liquified and shipped as liquid, and transported like liquid oxygen. This half-crazy idea developed into a less crazy scheme to store gas for domestic use as methane; the storage capacity for the liquid for the same thermal energy would be about a thousand times less than that for the gas. Another idea, that it might be used as a liquid for motor transport, was fully investigated in the Imperial College during the Second World War; and it was shown to be a possible substitute for petrol. The carbon content of coal could be more easily converted to methane than to oil, so that possible supplies of a fuel alternative to petrol were great. Omnibuses were run for about 25,000 miles in the public service on liquid methane in special vacuum-jacketed tanks, which were developed for the purpose. When petrol became available again, the interest flagged; but it is possible that it might revive with methane drainage, or possibly when a store of gas is required to meet special loads. The section at the Imperial College for research on low-temperature technology arose out of our interest in these technical problems relating to the use of methane.

BIRD CONSERVATION IN EUROPE

THE Fifth Conference of the European Continental Section of the International Committee for Bird Preservation was held in Bologna, Italy, during May 14–16 under the chairmanship of Dr. Boje Benzon (Denmark). The meeting was attended by delegates of the national sections for Austria, Denmark, France, Germany, Great Britain, Italy, the Netherlands and Switzerland, together with representatives of the International Union of Biological Sciences, the International Union for the Protection of Nature and the Conseil International de la Chasse.

One of the most urgent questions discussed was oil pollution of the sea and consequent destruction of sea-birds. A preliminary survey made by the Royal Society for the Protection of Birds in conjunction with the British Section of the International Committee for Bird Preservation during the winter and spring 1951–52 as to the numbers and species destroyed in this way around the coasts of Great Britain showed 70 per cent of the birds found on the beaches were gulls and 16 per cent guillemots and razorbills. A similar survey carried out in Holland produced a different proportion of birds destroyed, 45–50 per cent being guillemots and only a few gulls. The percentages of other species affected also varied in the two countries. On the coasts of Denmark, scoters and eider ducks appear to be the most frequent victims.

A valuable report on the work being done in the analysis of deposits of oil waste to endeavour to trace the type of ship from which oil pollution has emanated was contributed by the British Section. Work carried out so far shows that specimens of oil deposits taken from beaches were wholly of petroleum origin and identifiable as two kinds of oil, waxy sludge or bottoms as deposited in the tanks of tanker vessels carrying crude oil, and heavy fuel oil. The analysis of oil obtained from the feathers of birds, on the other hand, proved to be fuel oil only. The presence of the latter oil in the sea probably follows the pumping by ships of bilges and ballast tanks, and as this oil remains as a viscous film when spread on water it is more likely to cause oiling of birds. The urgent necessity for such research as a means of assisting to solve the problem of prevention of oil pollution of the seas was appreciated by the representatives of all countries present. A resolution was passed directing attention to investigations in progress into the nature and sources of the types of oil pollution and the need for further facts on important parts of the problem, pressing for completion of the investigations, and asking the governments concerned to give these the fullest support with the view of reaching a constructive and acceptable solution to this serious trouble.

The protection of migratory birds is a question of prime importance to the countries of Europe, particularly with regard to those species which are considered as sporting birds and as suitable for food. Reports on migratory birds giving lists of those regarded as sporting birds, the close-times accorded to both sporting and other migratory birds and details of any species which have decreased, with suggestions as to the reasons, were furnished by the national sections of France, Germany, Great Britain, Greece, Italy and the Netherlands. The interpretation of the term 'sporting birds' varies considerably in different parts of the Continent, thrushes being considered fair game in a number of countries, and in some all small passerine birds are regarded as suitable for the pot. In Germany and Italy, a decrease of all waders and water-birds is reported, and a similar situation is apparent in parts of France, whereas in Greece there is a serious decrease in all sporting migratory birds. Whether other migratory birds are decreasing or not is more difficult to observe, and some countries had no information on this point; in Italy, however, a decrease in swallows and swifts is attributed to the ever-increasing use of insecticides. The need for the further protection of migratory birds was evidenced by the passing of resolutions pressing that shooting in spring should be everywhere prohibited, whether on coasts or inland, and that all methods of capturing birds *en masse* (nets, snares, bird-lime, etc.) should be forbidden.

The proposal put forward at the Conference held in Uppsala in 1950 that an endeavour should be made to establish a series of bird reserves on the main migration routes in Europe was also reported upon. The Camargue Nature Reserve, in the Rhône delta, which was created, and is administered by, the Société d'Acclimatation de France and where protection is afforded to many migratory birds on passage to other European countries, was specially discussed. Grave concern was expressed over the possible effects upon bird-life of a further extension of economic exploitation of the area. A resolution was passed in which it was stated that the Conference considered that the unique and irreplaceable scientific significance of the Camargue as a nature reserve of first-rate European importance ought to be officially recognized by agreement between the interested governments, and requested the French Government to accept the principle that large parts of the Camargue should be permanently safeguarded not only for future generations of scientific workers and friends of Nature, but also for the conservation of the stock of migratory birds on their way to other European countries. The Conference also invited the Société d'Acclimatation de France to accept the help of other countries.

Birds which are a menace to other species present a difficult conservation problem, and the situation with regard to the herring gull in the countries bordering the North Sea was the subject of reports from Denmark, Germany and the Netherlands. A survey made of the herring gull colonies in the three countries showed a total of 56 colonies, of which 31 consisted of more than 1,000 pairs, 12 from 100 to 1,000 pairs and 13 less than 100 pairs. Various lines of investigation are being pursued, such as ringing, study of food taken by the birds and the effect they have on other species nesting in the proximity of colonies. Results of measures taken to control the numbers of gulls were also reported upon. In Holland, herring gulls prove a menace to other species and the control of their numbers is considered essential; in Denmark, on the other hand, they are found to cause little damage to other species and are considered a necessary part of the ecology of sea-bird colonies. Ringing results have established that German herring gulls are non-migratory and, though not yet complete, the Dutch results indicate that in the Netherlands the birds do not wander far from their original nesting grounds.

The International Convention for the Protection of Birds which was signed *ad referendum* at a Government Conference in Paris in 1950 has made no further progress, the majority of national sections present reporting that their respective governments were awaiting the passage of national legislation before adhering to the Convention, though some signified that their governments would not long delay.

The investigations into the status of the Anatidæ being carried on in various countries were reported upon, and Dr. Edward Hindle, honorary director, presented a report on the work of the International Wildfowl Research Institute which was set up in London to correlate these investigations and act as a centre of information.

Other subjects dealt with were the conditions of birds transported alive from tropical countries to Europe, the use of birds' feathers in millinery and excessive shooting and netting of birds in parts of France.

CENTENARY OF THE AMERICAN GEOGRAPHICAL SOCIETY

THE American Geographical Society of New York, the oldest society of its kind in the United States, has now reached a ripe age for an American institution —one hundred years. It ushered in its centennial year with a largely attended dinner last autumn, and on May 22, 1952, it celebrated its 'Charter Day' with a convocation at which Mr. John Foster Dulles spoke and an exhibition was formally opened. The approaching centennial was a factor leading to the choice of the United States as the meeting-place for the Seventeenth International Geographical Congress, which is to be held in Washington in August. At special ceremonies the Society will entertain and honour foreign geographers on their arrival in New York *en route* to the Congress.

The Society is twenty-one years younger than the Royal Geographical Society and has had a somewhat comparable career*. Its founders consisted of merchants, ship-owners, and other business and professional men—among them, an influential group of newspaper publishers, editors, historians and writers. Until 1871 the institution was called "The American Geographical and Statistical Society", and about a third of the papers read before it at that time had to do with statistics. From the beginning the Society has kept up a consistent interest in exploration, though to a lesser degree than its sister Society in London. It aided the American Arctic expeditions of Kane, Hayes, Hall, Greely, Schwatka, and De Long, during the 'fifties, 'sixties and 'seventies, and later was closely associated with Peary (who served as president during 1903–6), Stefansson, Rasmussen, Wilkins, Byrd, Louise A. Boyd, Ronne, and many other explorers. Judge Charles P. Daly was president from 1864 until his death in 1899 and did more than anyone else during its first half-century to establish the Society on firm foundations. In 1874 he said that one purpose of geographical societies was "to press the importance of scientific attainment . . . upon all who are ready to encounter the toil, the privation, and the peril that are incident to such noble undertakings [that is, exploring expeditions], that they may bring back what will be honourable to themselves and useful to the world". The Royal Geographical Society and the American Geographical Society have adhered to this principle.

---

* For further details on the history of the Society see the following recent publications by Dr. J. K. Wright, director during 1938–49 of the Society: "Geography in the Making. The American Geographical Society, 1851–1951" (New York, published by the Society, 1952), reviewed on p. 89 of this issue of *Nature*; "The American Geographical Society: 1852–1952", *The Scientific Monthly*, 74, No. 3, 121 (March, 1952); "British Geography and the American Geographical Society, 1851–1951", *Geographical Journal*, 118, 153 (1952).

Both Societies have also striven to advance geographical education along modern lines in their own countries. In the mid-'eighties the Royal Geographical Society took the lead in the movement that established geography in British universities and effected its improvement in the schools. Similarly, in the mid-'nineties the American Geographical Society adopted a policy of close collaboration with teachers. It gave moral encouragement and material assistance to the Association of American Geographers during the latter's formative period. The Association, consisting largely of university geographers, was founded by Prof. W. M. Davis in 1904 for the development of geographical research. The American Geographical Society also came to the rescue of the school teachers' *Journal of Geography* when that estimable little magazine was about to expire in 1918. In 1912 the Society conducted an excursion through the United States to the Pacific coast and back. Ninety American and forty-three European geographers participated, the Europeans as guests of the Society through the generosity of Mr. Archer M. Huntington, the Society's outstanding benefactor. This extraordinary trip forged new bonds of friendship, esteem and collaboration across the Atlantic—bonds that held firm despite the First World War and that help to explain a broadening of the Society's world outlook in the years that followed.

Isaiah Bowman (1878–1950) was the first director; he served from 1915 until 1935, when he resigned to assume the presidency of the Johns Hopkins University. Before his appointment, the Society had confined its activities almost entirely to publishing a journal, building up an excellent library, holding semi-popular lectures, and awarding medals and other honours. Dr. Bowman more than quadrupled the membership and raised the scientific standards of the journal, which was renamed *The Geographical Review* in 1916. He inaugurated several series of monographic publications, including the well-known Research Series and the Special Publications, in which some eighty works have appeared to date. Furthermore, during Dr. Bowman's administration, chiefly through his initiative, and with the financial support of Messrs. Huntington, J. B. Ford and others, the Society embarked upon a new type of enterprise: the conduct of large programmes of original investigation both by members of its staff, who were added for the purpose, and by outsiders under the Society's general supervision. These have dealt especially with techniques of exploration and cartography, and with the geography of Latin America, of the polar regions, and of pioneer settlements in different parts of the world. They have yielded fruit in new instruments and techniques of reconnaissance surveying and map-making, in a great "Map of Hispanic America on the Scale of 1 : 1,000,000" (107 sheets), and in many other maps, monographic works, and periodical articles. In these ways the Society extended its influence and gained recognition as a genuine research institution.

The American Geographical Society is now crossing the threshold of its second century under the invigorating leadership of a British geographer. In 1950 Dr. George H. T. Kimble, formerly of the University of Reading, and later professor of geography in McGill University, Montreal, was appointed director. He is putting into effect a reformulation, recently adopted by the Council, of the Society's time-tested policies. Research is to be maintained and accelerated. The Hispanic-American programme will continue, though on a reduced scale. Fresh fields are being energetically opened: the geography of diseases, the study of glaciers in relation to climatic changes, and investigations of the distribution and use of natural resources. The Society is also seeking new ways and means whereby geography may be applied to useful purposes and is striving to "bridge the gap between geographical scholarship and teaching", a gap that yawns altogether too wide for safety, not only in the United States but also in most of the other countries of the world.

OBITUARIES

Prof. H. A. Kramers

An untimely death has removed from the world of physical science one of its most original and inspiring figures. Prof. H. A. Kramers was professor of theoretical physics in the Technical University of Delft.

Prof. Kramers was universally respected as a master in many fields, skilful alike in putting to use the most subtle methods of algebra and in bringing to light the essential physical features of the most varied phenomena. He was universally liked as a man: everyone who came into touch with his warm and fine personality yielded to its charm and mingled respect with affection. His shrewd judgment of human affairs and his interest in people made him eminently suitable for the responsible positions he occupied in international bodies ministering to the common needs of physicists of all nations. Deeply concerned with ethical problems, he regarded the control of nuclear energy as a most compelling task. His work in the Atomic Energy Commission of the United Nations Organization was a sacrifice accepted in all simplicity: he came back with his health irreparably undermined. Although in his last years his curiosity and enthusiasm for the new advances of physics were as youthful as ever, he had not recovered the vigour of his former days. Yet he strained to the last his failing strength in the fulfilment of his unselfish work for science.

To the physicists of my generation, who knew of the heroic days of quantum theory only by the tradition received from our elders, Kramers had about him the glamour and the wisdom of the pioneer. His early association with Bohr, his later collaboration with the young Heisenberg, exerted a marked influence on the shape taken by the development of quantum mechanics. He had been brought up against the background of the Lorentzian tradition, still very much alive even to this day in Holland, and the incisively critical spirit of his teacher Ehrenfest could not have failed to leave its mark on him. Kramers's role in this first period of his scientific life has thus been to carry over, in a highly original form, the great classical traditions of Dutch physics into the growing tide of quantum theory. This he did, above all, by his masterly analysis, in the spirit of Bohr's correspondence argument, of those optical problems which had absorbed Lorentz's attention so fully. His very first attempt, on the intensities in the Stark effect, became at once a model for the methods of quantum theory in its initial stage; so much so that when Schrödinger first wanted to test the powers of his wave-mechanics, he quite naturally took up that very problem for comparison. But a still more decisive advance was Kramers's reformulation of the theory of optical dispersion, which paved the way to Heisenberg's great discovery.

After his return to Holland, the task he accomplished, though of a different character from his work in Bohr's circle, was no less honourable and no less exacting. If the old Dutch tradition of theoretical research in physics has been so brilliantly upheld and continued along the lines of quantum theory, it is due in no small part to the powerful influence of Kramers's personality. By his versatile activity he contributed much himself to the development of the methods of quantum mechanics and to their application to many fundamental problems of atomic physics. But who will tell how much he stimulated his fellow-workers by his example, his experimental colleagues by his advice, his pupils by his guidance, his students by his teaching? Besides all this, there was Kramers the man, to whom nothing human was foreign. His friends would never seek in vain his wise counsel in affairs of public import, or his warm sympathy in their private worries. His help often came unsought, and sometimes a hint, unobtrusively preferred, would make you realize that, unknown to you, he had given long and careful thought to your problems. His name will live in the annals of science; his gentle image in the hearts of his friends. L. ROSENFELD

Prof. Louis Guillaume

THE death, following an accident at Strasbourg on May 29, is reported of Prof. Louis Guillaume, Ingénieur en chef at the Bureau de Recherches Géologiques et Géophysiques in Paris, and well known and respected among British geologists.

Guillaume, who was born in 1894, held academic posts at both Caen and Strasbourg, and in 1941 helped to found the Bureau des Recherches Géologiques et Géophysiques, the object of which was to co-ordinate, facilitate, and if need arose, to initiate, the search for useful economic materials in France. He was the author of numerous scientific articles in the fields of palæontology and stratigraphical geology, and his premature death deprives his colleagues of his collaboration in a number of important works, particularly on hydrogeology, for which he had assembled an extensive and valuable documentation.

Guillaume was a fervent anglophile and had made many friends in Great Britain; they will mourn the passing of a generous and dynamic personality.

A. C. TOWNSEND

NEWS and VIEWS

Medical Protozoology in the University of London: Prof. H. E. Shortt, C.I.E., F.R.S.

PROF. H. E. SHORTT, who has held the chair of medical protozoology in the University of London at the London School of Hygiene and Tropical Medicine since 1947, is to retire in October. Prof. Shortt was formerly in the Indian Medical Service, and has made discoveries of fundamental importance in the field of tropical medicine. During his work in India on the etiology of kala-azar, carried out over a period of twenty-five years, he proved that the transmitting agent was *Phlebotomus* and contributed profoundly to the knowledge of this disease and its causal organism. In recent years he has carried out brilliant researches on the life-cycle of the malaria parasites, in which Dr. P. C. C. Garnham collaborated, and for which they were jointly awarded in 1951 the Darling Medal and Prize given by the World Health Organization.

Dr. P. C. C. Garnham

DR. P. C. C. GARNHAM, who is to succeed Prof. Shortt, was in the Colonial Medical Service during 1925–47 and was director of the Division of Insect-borne Diseases in Kenya during the last four years of his service. He has published numerous original articles, many of which are concerned with malariology, a subject in which he has specialized and achieved distinction. In Kenya he carried out important research not only on malaria but also on relapsing fever, plague, onchocerciasis and jungle yellow fever. The epidemiology of these diseases and the bionomics and control of their insect vectors were his special concern. An outstanding success in this field was his discovery of the use of DDT in destroying the larval stages of *Simulium neavei*, the vector of onchocerciasis in Kenya and other parts of East Africa. This method of control has resulted in the complete eradication of the insects in certain endemic foci. On joining the staff of the London School of Hygiene and Tropical Medicine as reader in medical parasitology in 1947, he participated in the experimental work which led to the first discovery of a pre-erythrocytic stage in the life-cycle of mammalian malaria parasites. His collaboration in this work and in the subsequent researches which established the presence of this long sought-for missing link in the life-cycle of the human malaria parasites, *Plasmodium vivax* and *P. falciparum*, has earned for Dr. Garnham an enduring name in the history of tropical medicine research.

Institution of Mining Engineers: President for 1953–54

MR. J. CECIL MITCHESON has been elected president of the Institution of Mining Engineers for the year 1953–54, and will succeed Mr. R. J. Weeks at the annual general meeting to be held next January. Mr. Mitcheson comes of an old mining family, his great-grandfather having worked with George Stephenson at the Old Killingworth Colliery; both his grandfather and father were also associated with the industry. Mr. J. C. Mitcheson was educated at Bootham School, the Royal Military Academy, Woolwich, and the University of Birmingham, where he graduated B.Sc. in mining. After obtaining his colliery manager's certificate, he was appointed lecturer in coal mining and demonstrator in mine rescue in the University of Birmingham under the late Prof. K. Neville Moss. In 1924 he returned to the mining industry to assist his father in his consulting practice in the Midlands, and was later appointed managing director of the Birch Coppice Collieries of Morris and Shaw, Ltd. During the Second World War he was group production director for the Warwickshire Coalfield. When the mines were nationalized, Mr. Mitcheson served for a time as mining development engineer to the West Midlands Division; later he resigned to take up consulting work and to look after the interests of his former company. He has visited mines in France, Germany, Belgium, Spain and the United States, and has recently reported on the brown-coal deposits of Iceland for the Icelandic Government.

Paris to London Television Relay

DURING the period July 8–14, a new and advanced experiment in the international exchange of television programmes was carried out between Paris and London. By co-operation between Radiodiffusion et Télévision Françaises and the British Broadcasting Corporation, a part of each day's programme in the public television service in Great Britain originated in Paris. Due to the failure to achieve uniformity in the television standards in use in Europe, it was necessary to convert the television signals from the French 819-line system to the British standard of 405 lines. This conversion was carried out at Cassel by equipment developed by the B.B.C. in which the picture with the original number of lines on the screen of a cathode-ray tube is re-scanned by a television camera operating on the number of lines normally used at the receiving end of the circuit. Earlier experimental work had shown that the success of this technique depended on the use in the picture tube of a screen having a phosphor with a decay time comparable with that necessary to scan a single frame of the television image. By this means the camera views an image that is virtually continuous during each frame. The phosphor used in the cathode-ray tube at Cassel is zinc beryllium silicate, which has an exponential decay characteristic such that the brightness of any particular point in the image falls to about 28 per cent of its original value during the time of scanning one frame. A Marconi Image-Orthicon camera was used to re-scan the picture at the 405-line standard. From Cassel the pictures were transmitted to London by a series of radio links. Apart from some intermittent technical faults with both the sound and vision signals, the experimental programmes could be regarded as very successful in indicating the possibilities of exchange of programmes between European capitals and other places separated by a few hundreds of miles. As a combined operation between R.T.F. and B.B.C., this achievement marks a new step forward in the development of outside television broadcasting.

The Chemical Society of the University of Edinburgh

FOR his presidential address to the Royal Society of Edinburgh delivered on July 7, Prof. James Kendall spoke on "The First Chemical Society, the First Chemical Journal, and the Chemical Revolution". He discussed the first volume of the proceedings of the Chemical Society of the University of Edinburgh, which was discovered a few years ago in the library of the Royal Irish Academy and has since been presented to its original owners in the University of Edinburgh (see *Nature*, 159, 867; 1947). The volume is a well-bound folio of 452 pages in copperplate manuscript, containing thirty-two dissertations on topics of chemical interest. Although the communications presented are not of major scientific importance, they do afford a unique record of contemporary chemical thought. In particular, they disclose one fact of significant historical interest, namely, that Joseph Black, commonly regarded as among the last to accept the 'chemical revolution' of Lavoisier, must have been among its earliest advocates, since the majority of his students were already converts to the oxygen theory of combustion in 1785–86. The penultimate paper, by Mr. John Carmichaell, merits special consideration. It consists of a violent attack upon the long-established doctrine of phlogiston, which Lavoisier overthrew, and concludes with a quotation from Virgil applicable thereto: Venit summa dies (Its last hour has arrived). That pronouncement was obviously endorsed by Mr Carmichaell's colleagues, since on the title-page of his medical graduation thesis in 1787, where he continues the attack, he proudly announces himself as "Extraordinary Member and President for the Year of the Chemical Society of Edinburgh". This thesis was almost certainly one of two sent by Black to Lavoisier in 1790 as proof that Edinburgh students, while enjoying "the most perfect liberty of chuseing their philosophical opinions", had in general embraced his system. Incidentally, Mr. Carmichaell was one of the few original members of the Society who was a native Scot.

International Commission on Glass

THE International Commission on Glass held its annual meetings under the presidency of Prof. W. E. S. Turner throughout the week June 30 - July 5. The first two days were spent in London, in part in the rooms of the Institute of Physics, and in part at the Research Laboratories of the General Electric Co., Ltd., Wembley; the meetings on the other four days were held in Sheffield at the Department of Glass Technology in the University. Representatives of Belgium, France, Germany, Great Britain, Holland, Japan, Spain, Sweden, Switzerland and the United States attended. The technical work of the Commission occupied three full days, one of them devoted to an open session; the two other days to committee work on a variety of subjects classified under the group headings of glass literature; chemical properties of glasses; physical properties of glasses; glass furnace problems. Reports were presented on tasks or projects previously undertaken by affiliated organizations; agreements were reached on a number of fundamental issues, and plans were prepared for further collaboration. The International Standards Organization sent, by invitation, two observers to the meetings. Among the events were visits to the Research Laboratories and the glass works of the General Electric Co., Ltd., and to the imposing new works—unique in Europe—at Harworth, near Doncaster, where the glass envelopes for electric lamps and radio valves are manufactured at tremendous speed. Prof. W. E. S. Turner, to whom illuminated addresses were presented from Germany and Japan, will, after being continuously in office for twenty years, retire from the presidency in 1953. He will be succeeded by Dr. B. P. Dudding, honorary secretary of the Institute of Physics and at present secretary of the Commission. M. Henri Vandecapelle, director of the Institut National du Verre, Charleroi, was appointed secretary-elect.

Problems of Land Reform in Under-developed Countries

IN the under-developed regions of the world there are many impediments to the improvement of rural living standards. Among them are the fragmentation of holdings, the concentration of land ownership in a few hands, high rents and insecurity of tenure, low wages, exorbitant taxation and inadequate provision for agricultural credit. In a report, entitled "Land Reform: Defects in Agrarian Structure as Obstacles to Economic Development", published by the United Nations' Department of Economic Affairs (pp. 101. New York: United Nations. 75 cents. London: H.M.S.O., 1951. 5s.), it is emphasized that it is the agrarian structure and, in particular, systems of land tenure which prevent a rise in the standard of living of small farmers and agricultural labourers. Land reform, however, if it is to be effective, must comprise improvement in all the social and economic conditions affecting farm life. Changes in the land tenure systems are more likely to lead to a rise in the standard of living of the rural community when they form part of a general programme than when they are undertaken in isolation. The provision of credit facilities, co-operative marketing, technical advice and health services are among the major services needed. The report points out that if steps are not taken to provide facilities of these kinds to newly established small farmers, many of the benefits which might be expected to result from reform of the land tenure system will be nullified.

Eradication of Bovine Tuberculosis from Cattle in Denmark

DENMARK, with some 1,600,000 dairy cows, has recently completed the eradication of bovine tuberculosis from among her herds, and is the first country in the world to guarantee that all exports of butter and cheese are from the milk of tubercle-free animals only. The occasion was marked by official celebrations in Copenhagen on June 13. The campaign was begun sixty years ago, when Prof. Bernhard Bang, of the Royal Veterinary College, Copenhagen, advocated the tuberculin-testing of all cattle, the isolation of the healthy animals, and the weeding out of reactors; its completion involved the slaughter of 318,000 reactors between 1934 and 1951 ("The Campaign against Bovine Tuberculosis in Denmark and its Eradication." By T. Mathiassen. Aarhus: by the Danish Federation of Dairy Associations. '*Re* Lur' branded butter and cheese: Order of Danish Ministry of Agriculture, March 27, 1952).

Ethics of Management

A STRIKING article in the current issue of the *Journal of the Institute of Personnel Management* (34, No. 319) is one by the Institute's director, Mr. H. E. Roff, on the ethics of management. Accepting the four-fold aim of industry as the provision of goods and services, the earning of profit on capital, the provision of employment and the provision of social and work satisfaction, Roff suggests that management has responsibility to the customer, the shareholder, the employee and the community, the latter including responsibility for preserving the amenities of Britain, making effective use of natural resources, helping to produce democratic citizens and, finally, teaching the new generation of managers. The journal also contains an account of the workshop for elderly men at Rubery Owen and Co., an examination of the scientific study of human relations in industry, the report of a morale survey in a Danish department store, and the part played by trade unions in German industry. There are also some interesting notes on the training of shop stewards and the employment of older workers as well as the usual reviews of books and periodicals.

Imperial College of Science and Technology, London: Report for the Year 1950-51

THE forty-fourth annual report of the Governing Body of the Imperial College of Science and Technology, London (pp. 55; from the College at South Kensington, London, S.W.7; 1951), covering the year ended July 31, 1951, refers to the further special grants of £3,000 made by the University Grants Committee in 1950–51 rising in 1951–52 to £4,000 for the provision of bursaries for postgraduate students in engineering. The first of the projected extensions to the chemical technology building and the new chemistry laboratories were completed during the year, adaptation of the Union building was nearing completion and the erection of laboratories for mineral dressing by adaptation of part of the Bessemer Laboratory is expected to be complete in August 1952. In spite of continuous progress in developments on the technological side, increasing costs have checked the steady advance in the quality and quantity of the work of the College during the first four years of the quinquennium. A deficit of more than £9,000 was incurred in 1949–50, and much larger deficits are anticipated in 1950–52. The finances have accordingly been closely examined to determine the directions in which economies are possible with the minimum reduction of efficiency. Capital grants from the University of London for new construction and equipment totalled £154,290; but room for expansion constitutes a serious problem. The plan for a South Kensington site has come no nearer to fruition; but the acquisition of the sites at 181–5 Queen's Gate and of the underlease of the property at 177 Queen's Gate should provide sufficient room for necessary normal development in the next five or ten years. Appendixes to the report include, besides the statement of accounts, a list of publications during 1950–51, arranged by departments.

Interpretation of Seismograms

PRIOR to the year 1930 seismologists were obliged to acquire information required for the interpretation of seismograms piecemeal from papers and portions of books on seismology, and from a careful study of their own particular instruments. In 1930 they became indebted to Dr. Frank Neumann, mathematician of the United States Coast and Geodetic Survey, for collecting these data and for making them available in mimeographed form. With the advance of the science of seismology it has now been necessary for Dr. Neumann to revise and enlarge his original work on this subject, and seismologists are now indebted to the Coast and Geodetic Survey for printing the work as Special Publication No. 254, "Principles Underlying the Interpretation of Seismograms". This work, which has been brought thoroughly up to date, is written for the Seismograph Station director, for the student who is beginning his career as a seismologist, or for the amateur seismologist. The reader is provided with basic background information pertaining to the origin and transmission of seismic waves and the recording characteristics of the principal types of seismographs now used in the long-range detection of earthquakes, including short-period instruments. The established fundamentals of earth structure, upon which seismic wave propagation is dependent, are set forth, and travel-time tables for the major phases are discussed; graphs of the Gutenberg–Richter tables for four depths of earthquake focus, and published during 1934–39, are given. It is to be noted that an error of one second in determining the arrival time of the primary or *P* phase will result in epicentral distance errors ranging from 8 km. at a distance of 1,000 km. to 22 km. at a distance of 10,000 km. Rather more than ten years ago, Gutenberg and Richter introduced the earthquake magnitude scale, based on measurements of seismograms, to replace the earthquake intensity scales used previously. This logarithmic magnitude scale is described in detail. An increase of one unit in magnitude signifies a 63-fold increase in energy, and on the Gutenberg–Richter scale an earthquake of magnitude 5 would release 10^{21} ergs of energy. Copies of interpreted seismograms are given as illustrations in the publication.

The Blue Sun of September 1950

The results of spectrophotometric observations of the blue sun, made at Edinburgh between 15h. 20m. and 15h. 25m. U.T. on September 26, 1950, have been described by R. Wilson (*Mon. Not. Roy. Astro. Soc.*, 111, 5; 1951). The 36-in. Cassegrain reflector of the Royal Observatory was used with the two-glass prism train of the attached Hilger universal spectrograph, giving the respective dispersions 132, 45 and 28 A./mm. at $H\alpha$, $H\beta$ and $H\gamma$. Very full details of the procedure and the deductions are given in the paper, at the end of which appears a summary of the conclusions. The layer causing the phenomenon was due to extensive forest fires in Alberta on September 23, 1950, the smoke from which was carried by upper winds to Europe, where the effect was quite different from that in America. Over the latter continent at various times and places there was complete darkness, and when the sun was visible it was purple or blue, while the scattered light in the sky produced shades of orange, purple or blue. Over Edinburgh on the afternoon of September 26 the smoke was observed, and the sun, seen quite clearly through the haze, was a deep indigo blue. According to E. M. Elsley (*Weather*, 6, 22; 1951), the scattering particles were globules of oil, caused by the distillation of wood, and the scattering theory predicted various features which were experimentally verified by Wilson's investigations. These particles were dielectric in nature and very homogeneous in size and constitution, and there appears to be the possibility that there was another system of particles in the layer, producing a neutral extinction. Using a relation deduced between the diameter and the refractive index of the scattering particles and assuming the latter to be about 1·5, which is near the value for most organic oils, the diameter of the particles would be of the order of one micron. If there was the other system of particles in the scattering layer, it is suggested that their most likely constitution was carbon, and it is possible that their size could be the same as that of the uniform dielectric particles. Communications in *Nature* of September 29, pp. 545 and 554, and December 22, p. 1086 (1951), also discussed this topic.

Exhibition of Geometry at Chicago

The Illinois Institute of Technology has arranged an exhibition of geometry at the Chicago Museum of Science and Industry, and Prof. Karl Menger has written an attractive 34-page guide-book, with the title "You will like Geometry". The most striking feature of this is the large number of beautiful diagrams. The subjects treated are very varied. There are simple constructions of plane geometry, including some of a puzzle type which do not appear in the usual text-books. There is also a section on the regular solids, including Kepler's star-faced solids and Poinsot's star-cornered solids. Other parts of the guide book deal with more advanced mathematics, such as the theory of groups, which is introduced with reference to operations on triangles and other geometrical figures. An account is given of the 'universal curve', discovered by the author, which has the property that every curve of our space can be deformed into one of its parts. As the preface claims, "Geometry is amazing and ingenious and beautiful and profound; and, most important, it is alive and growing".

Announcements

'Open days' are being held at the Chemical Research Laboratory, Teddington, Middlesex, during September 23–26. Industrial firms wishing to send representatives and who are not already on the mailing list should apply to the Director, before August 31, for invitations for September 23 (afternoon), September 25 or 26 (morning or afternoon).

Pakistan's first seismological research station is now being built in Quetta with the technical assistance of Unesco. The new service would be grateful for reprints of seismological papers published before 1948 and for back numbers of journals, which should be sent to the Pakistan Meteorological Service, Geophysical Division, Kings Road, Quetta, Pakistan.

Messrs. Blundell Rules, Ltd., Chaul End Lane, Luton, Beds, have issued a small handbook of 22 pages (price 6*d*.) describing their range of slide rules, and giving examples of the uses of the various patterns. Thus, in addition to the usual rules in various styles graduated for simple mathematical operations, there are others with log–log scales, commercial calculators, electricians' scales with appropriate quantities, and a timber calculator. Most of these scales are made entirely of a white plastic material, based on vinyl chloride–vinylidene chloride copolymers, with a 'satin' finish. It is claimed to be resistant to water, most chemicals and fungi. It is strong, and the scales are sharp and clear; in some patterns the tension of the slide can be adjusted. Model A.G.1 (£1 13*s*.), a simple general-purpose rule, has the usual *A*, *B*, *C*, *D* scales, and also scales for reciprocals, cubes and mantissæ; additional red lines on the cursor provide for finding areas of circles of given diameter.

Erratum. In the communication entitled "Cellular Permeability of Yeast to Metallic Ions", by E. Quagliozzi and A. Rescigno, published in *Nature* of July 5, p. 35, the first equation should read:

$$\frac{V}{L}\,\frac{\mathrm{d}x}{\mathrm{d}t} = -\,v\,\frac{x}{Lb/V} + v\,\frac{(x_0 - x)\,V/L}{a}\,;$$

and the second should read:

$$\frac{x}{x_0} = \frac{a\,.\exp\left(-\,v\,\dfrac{a+b}{ab}\,t\right) + b}{a+b}\,.$$

The second reference in the footnote should be disregarded.

BIOSYNTHESIS OF CAROTENES IN RIPENING TOMATOES

By DR. T. W. GOODWIN and MALINI JAMIKORN
Department of Biochemistry, University of Liverpool

PORTER and Lincoln[1] have recently put forward a theory of carotenogenesis in tomatoes. This scheme is based mainly on the results of pigment analyses carried out on the ripe fruit of various specially-bred crosses. From these a series of polyenes was obtained, differing from each other by four hydrogen atoms. As the members of the series could always be detected in every cross, it was postulated that the fully unsaturated carotene, lycopene, is formed from more saturated precursors by the stepwise removal of four hydrogen atoms, thus: perhydrophytoene → phytoene → phytofluene → ζ-carotene → neurosporene → lycopene. Lycopene is then assumed to become isomerized, in amounts varying according to variety, to α-, β- and γ-carotenes. The scheme was justified on genetic grounds. Porter and Lincoln emphasize, however, that a different mechanism may operate in other plant tissues such as green leaves.

The pioneer observation of Duggar[2], that ripening of excised tomatoes above 30° results in the inhibition of lycopene synthesis but not that of carotene, has frequently been confirmed[3]. Furthermore, as soon as the ripening temperature is reduced to 30° or below, lycopene synthesis is resumed and proceeds normally.

It was decided to find out what happened to the members of the Porter–Lincoln series other than lycopene when the synthesis of this latter carotene was inhibited by ripening excised tomatoes at high temperature. In particular, the variation in the phytofluene content was followed quantitatively, as this polyene occurs in reasonable amounts in ordinary commercial varieties, whereas most of the other members (for example, ζ-carotene and neurosporene) are only present in traces.

Methods and Results. Tomatoes were removed from the vine while still green as soon as the very first signs of ripening appeared. They were divided into four groups and these ripened at either 0°, 15°, 30° or 37°. Samples were taken for analysis once every three days for twelve days. The pigments were extracted and separated chromatographically according to the procedure recently described in detail by Goodwin[4]. α- and β-carotenes, lycopene and phytofluene were determined quantitatively, and the presence or absence of ζ-carotene and neurosporene was noted. Phytoene was never present in detectable amounts.

The results obtained are recorded in the accompanying table, from which the following conclusions can be drawn.

(1) It is confirmed that lycopene synthesis is inhibited at temperatures above 30°; there is, however, no concomitant accumulation of phytofluene or other members of the Porter–Lincoln series.

(2) The synthesis of the members of this series is equally inhibited under conditions inhibiting lycopene synthesis.

(3) Although all members of the series tend to appear together at the same stage of ripening, the rate of accumulation thereafter is not necessarily the same; for example, at 30°, from the ninth to the twelfth day of ripening, the amount of lycopene increases tenfold, whereas that of phytofluene is only doubled.

(4) The production of both α- and β-carotene is only slightly inhibited by ripening above 30°.

(5) Synthesis of all polyenes is inhibited in tomatoes held at 0°; but, again, that of lycopene most of all.

(6) No member of the Porter–Lincoln series is present in green (unripe) tomatoes.

Discussion. There seems little doubt from this and previous work that the major route of α- and β-carotene synthesis in normal tomatoes is a process entirely separate from the mechanism producing the Porter–Lincoln series. It is probable that α- and β-carotene can also be synthesized by a mechanism very similar to that producing the Porter–Lincoln series, but this can occur only to a very minor extent. The present results suggest that certainly not more than 15 per cent is formed in this way; but further observations are required before an accurate assessment can be made. Additional evidence that carotene can be produced in tomatoes by this second route comes from the results of Kohler, Lincoln, Porter, Zscheile, Caldwell, Harper and Silver[5], who produced a cross in which the carotene content of the ripe fruit was increased from a normal value of about 6 μgm./gm. to 101 μgm./gm.; this increase appeared to be almost entirely due to reduction of lycopene synthesis, for the total amount of carotenes present was not altered. Accepting the biosynthetic mechanism postulated by Porter and Lincoln, breeding in

SYNTHESIS OF POLYENES IN TOMATOES RIPENED AT DIFFERENT TEMPERATURES

	Amount present (μgm./gm. wet wt.)			
	3 days ripened	6 days ripened	9 days ripened	12 days ripened
Ripening temperature, 0°

ζ-Carotene Neurosporene	absent	absent	not detectable	not detectable

* At 15°, the selection for six days was at a more advanced stage of ripeness than that for nine days.

this case can be assumed to have caused a shift in the equilibrium lycopene ⇌ β-carotene.

The question then arises: What mechanism exists for the production of most of the α- and β-carotene synthesis in tomatoes if the Porter–Lincoln pathway is only of minor importance? The most reasonable assumption at the moment is that the synthesis is due to a 'carry-over' of the mechanism operating in green leaves. This assumption is made highly likely for three reasons: (1) it is known that no member of the Porter–Lincoln series exists in green leaves and, therefore, the biosynthetic mechanism there is probably different; (2) unlike the synthesis of lycopene in tomatoes, that of carotene in tomatoes and in isolated leaves[6] is not significantly inhibited by temperature above 30°; and (3) at 0°, when the complete physiological ripening process in tomatoes is almost entirely inhibited, the synthesis of α- and β-carotene still continues to a significant extent in the green fruit whereas that of lycopene is negligible.

Furthermore, although the carotenoids present in fungi and the non-photosynthetic bacteria include the Porter–Lincoln series as well as β-carotene[7-9], the synthesis of β-carotene in, for example, *Phycomyces blakesleeanus* can be completely uncoupled from that of the Porter–Lincoln series[10]. In green leaves, as just stated, none of the Porter–Lincoln series occurs. This appears also to be true for the photosynthetic bacterium, *Rhodospirillum rubrum*. This organism produces only a single fully unsaturated carotenoid, spirilloxanthin (together with small amounts of *cis*-isomers)[11], and no evidence has yet been obtained of the presence of any member of the Porter–Lincoln series[12].

Although it is reasonable to assume that all the members of the Porter–Lincoln series are synthesized via very similar routes, there is as yet no conclusive biochemical evidence establishing the claim of Porter and Lincoln that the more saturated members are precursors of the more unsaturated ones. It is possible that the reactions proceed in the reverse direction to that envisaged, or that, as suggested by Goodwin[3], the members of the series are formed by a number of parallel syntheses which would not involve the utilization of any member as an intermediate in the formation of another.

Whatever the final outcome of experiments designed to test the stimulating hypothesis of Porter and Lincoln, it is clear that two mechanisms of carotenogenesis exist in ripening tomatoes. In one, the synthesis of most of the α- and β-carotene is achieved by a very similar mechanism to that occurring in green leaves; in the other, the synthesis of the Porter–Lincoln series occurs. The exact mechanism of both these processes is still almost completely unknown.

We wish to thank Messrs. A. H. Kitson and C. Rutherford for a gift of suitable tomatoes, and Prof. R. A. Morton for his continued interest in this work.

INFLUENCE OF THIOUREA ON REPRODUCTION IN THE MINNOW

By Prof. E. J. W. BARRINGTON and A. J. MATTY

Department of Zoology, University of Nottingham

THERE has been accumulating considerable, if varied, evidence for the existence of some influence of the thyroid gland on the reproductive system of man[1], of other mammals[1-5] and of birds[6-8]. Evidence for such effects in the lower vertebrates, however, is much more limited and fragmentary, although it has been reported that thyroidectomy results in degeneration of the gonads in *Lacerta*[8] and *Triturus*[9]. Investigation of the situation in teleost fish has presented a particular difficulty, for the diffuse nature of the thyroid gland in that group has made surgical removal impracticable; but the discovery of anti-thyroid substances opened up the possibility of carrying out 'chemical thyroidectomy' by immersing fish in solutions of thiourea, and the use of this technique has produced some evidence of a retardation of growth and of the development of the external sexual characters in, for example, hybrids of *Platypoecilus maculatus* and *Xiphophorus hellerii*[10] and in *Lebistes reticulatus*[11].

In the course of an extended study of the thyroid gland of the minnow (*Phoxinus laevis*) we have kept a number of fish immersed in a 0·1 per cent solution of thiourea for several months under constant conditions of illumination and temperature (10° ± 2° C.), a control group being maintained under similar conditions in tap-water. It seemed likely from what was already known of the reproductive cycle of these fish[9] that an effect of the kind envisaged might be most readily demonstrated in the winter and early spring, and an initial experiment was accordingly begun on January 7, 1951. Little change took place in the thyroid gland during the first month of treatment; but by the end of the second month it was possible to demonstrate a substantial and statistically significant increase in the height of the follicle cells and a reduction in the internal diameter of the follicles, indicating that the synthesis of thyroid hormone was being impeded in much the same way as it would be in mammals. At the end of 67 days treatment, all the fish appeared in good condition, as judged by appearance and by the 'condition factor', calculated from the weight/length relationship[12], and a number were therefore killed on March 15 for serial sectioning of the gonads. A comparison of seven control males with seven treated with thiourea, a number known to be adequate for yielding consistent results[9], showed that whereas spermatogenesis was far advanced in the seminiferous tubules, it had largely been arrested at the spermatocyte stage in the latter group, five members of which showed no sperm at all and two showed only traces of them. The situation in the females was less striking; but a comparison of the oocyte diameter, using the same number of animals, showed that those treated with thiourea were, in fact, smaller, the difference between the two groups being statistically significant.

Some animals, although fewer than could have been wished, were kept alive for 154 days, until June 10, by which time all eight members of a group of control animals had developed to varying degrees such external sexual characters as head tubercles and scarlet coloration. In marked contrast to this, a group of nine animals treated with thiourea showed few signs of these; seven, for example, had no tubercles at all, and the other two had minute ones which could only be detected under magnification. The testis of the one male included in this latter group proved to be quite aberrant, lacking both sperm and stages of spermatogenesis, a condition difficult to interpret from a single specimen, but reminiscent of the "devastating" changes reported as occurring in the testes of thyroidectomized newts[13]; the testes of two control males were normal in appearance and full of sperm. The ovaries of four control females from this group, selected at random, were normal, with oocytes of a diameter approximating to those of mature eggs; but those of four females treated with thiourea possessed oocytes no larger than those of the 67-day fish: since, however, there were signs that these animals had not been feeding normally during the last four weeks of the experiment, we do not feel justified at this stage in attaching much weight to this last observation, although it is not necessarily lacking in significance.

While the results reported here seem to indicate a correlation between chemical thyroidectomy and a retardation of sexual activity in the minnow, they do not, of course, necessarily imply that the thyroid hormone normally exerts a direct influence upon the reproductive system of this animal; indeed, one cannot yet be certain that the consequences in fish of treatment with thiourea can legitimately be interpreted as physiological in nature. None the less, it is interesting to find increasing evidence of the existence of cyclical fluctuations in the activity of the thyroid gland of teleosts[14], related sometimes, it has been suggested, to spawning or to migration; and we ourselves, in work to be published elsewhere, have been able to demonstrate a statistically significant trend of increasing cell-height in the gland of the minnow during the winter and early summer. Our present knowledge of the endocrinology of the lower vertebrates is, however, so meagre that the significance of the facts is obscure in the extreme, and a discussion of them must be left for fuller treatment elsewhere.

In the meantime, one further point seems worth making. It has often been suggested that the apparent inhibiting influence of thyroidectomy on the reproductive system of the homothermous vertebrates might be a secondary consequence of reduced metabolic rate; in teleosts, however, such an explanation may prove to be less likely, for the available evidence, contradictory though it is in part, casts doubt on the existence of a marked calorigenic effect of the thyroid in that group. In studying such problems in fish, therefore, one may be analysing a simpler and, in evolutionary terms, more primitive situation than obtains in the higher forms, and it is hoped that work now in progress in this Department will test the correctness of this point of view. COMPETITIVE SUPPRESSION AND THE DETERMINATION OF LINKAGE IN MICRO-ORGANISMS

By J. L. JINKS

Agricultural Research Council's Unit of Biometrical Genetics, Department of Genetics, University of Birmingham

WHILE investigating the standard method of assessing the mutagenic activity of an agent by its enhancement of the back-mutation rate of strains of fungi carrying a biochemical mutation, Grigg[1] has demonstrated a marked suppression of the prototrophs (which arise from, and are used as a measure of, back mutation), by unchanged cells of the mutant strain, with which the experiment was started, and which are themselves incapable of growing on the medium used. Dilution of the spore suspension which was plated out gave an increase in the proportion of prototrophs recovered, presumably through a weakening of the suppression. Similar increases observed after treatment with reputed mutagens, which also kill a percentage of the spores, could therefore be due to a weakening of the suppressive effect and not to any rise in the back-mutation rate.

Kølmark and Westergaard[2] have shown that Grigg's criticisms do not apply to all tests of mutagenic activity made by the observation of back mutation, for on media containing excess nutrients competitive suppression does not occur. Indeed, it might be expected that competition will appear only where some nutrient is present in sufficiently small amounts for even the very limited activity of the non-prototrophs to cause its depletion. Since, however, suppression does occur under these, and possibly under other, so far unanalysed, conditions, it is essential for the correct interpretation of the results that, where such conditions are liable to be achieved experimentally, its effect should be recognized and its intensity evaluated.

Now clearly a similar suppression of prototrophs by spores themselves incapable of growth might occur where the prototrophs have come into being by means other than mutation. Techniques of demonstrating and estimating genetic linkages in micro-organisms are often dependent on the recovery of prototrophs, here arising by recombination of the genes in question, on selective media. In these cases, too, the prototrophs must grow in the presence of high concentrations of spores which, by virtue of their being non-recombinants or non-prototrophic recombinants, are incapable of growth. The recovery of the prototrophs, and hence the assessment of the linkages, might well, therefore, be disturbed by the occurrence of suppression similar to that which Grigg has found. Such a disturbance would be all the greater where, as in *Escherichia coli*, sexual fusion is itself rare, or where, as in the homothallic fungus *Aspergillus nidulans*, many of the fusions occur between nuclei of like genotype. In such species high concentrations of spores must often be plated in order to recover the prototrophs arising from the relatively rare fusion of nuclei of the appropriate types.

The occurrence of a suppression in *E. coli* is suggested by certain observations already in the literature, notably from studies of the effect of irradiation on recombination made by Haas, Wyss and Stone[3]. These authors used a concentrated inoculum, the cells coming from two strains which had complementary biochemical requirements. Only the prototrophs arising by recombination would grow on the medium used. The numbers of prototrophs increased with time of exposure to radiation, up to a maximum of thirty seconds at which a large number of cells were killed.

These results were taken as showing an increase in recombination resulting from some unanalysed effect of the radiation. It would appear, however, to be explicable by the suppression effect as Grigg has described it. We merely have to make the further, and not unreasonable, postulate that suppression of prototrophs can be produced by mixtures of two or more non-prototrophic genotypes, as it can by a uniform sample of one such genotype. The lethal action of the radiation would lead to a reduced concentration of viable cells and hence a reduced suppression of prototrophs just as in Grigg's case.

Any lethal agency should, on this view, lead to a similar rise in the rate of recovery of prototrophs (and hence to a similar rise in apparent frequency of recombination), and indeed these same authors, in collaboration with Bennet-Clark[4], have shown that treatment of the spore suspensions with hydrogen peroxide (except where this is vitiated by pre-treatment with catalase) and sodium azide, both of them killing agents, produced just this result. True, above a certain level the treatments led to a decrease in the absolute number of prototrophs recovered; but this could arise at any point where the killing of the prototrophs themselves was no longer offset by a reduction in the suppression, as would be the case when the suspension had been thinned out below a certain level by the general lethal action of the treatment.

A further observation of these authors[5] also fits into the same picture. They found that after plating irradiated *Staphylococcus aureus* on to media containing streptomycin or penicillin the number of colonies formed increased with dilution of the cell suspension. They were able to offer no explanation of this result, but the interpretation is obvious in terms of suppression. The streptomycin- or penicillin-resistant colonies which develop are the equivalent of prototrophs and they are growing in the presence of large numbers of non-resistant cells which, of course, are inactivated by the antibiotic. Dilution would thus, as before, reduce the suppressive effect which one might suppose to exist.

Evidence of a similar nature is provided by Newcombe[6]. He found that concentrations of non-prototrophs higher than half those normally used in linkage estimations in *E. coli*, that is, 2×10^9, led to an apparent reduction in the rate of mutation of *E. coli* to bacteriophage resistance. This could be due to a suppression of the prototrophs, which are in this case the resistant mutants, by the large excess of non-prototrophs, and not to a reduction in the actual rate of mutation.

Finally, there is the evidence from an investigation by Nelson[7] into the relationship between the concentration of the two parental types mixed together, and the number of prototrophic recombinants produced in *E. coli*. Although in some cases the relationship was linear over the concentrations of parental types investigated, in others there was a marked falling off in the number of prototrophs recovered as the concentration of parental types increased. Extrapolation of one of the curves shows that at the concentration of parental types normally used in linkage estimations, approximately half the expected number of prototrophs would be recovered.

The investigations of Nelson illustrate a further point, namely, that the extent of suppression, if any, is specific for a particular prototroph – non-prototroph – concentration – medium combination. Therefore, if more than one type of prototroph is selected for in the presence of a mixture of non-prototrophs, by a particular medium, there is the possibility of differential suppression of the prototrophs. If this is true, one would expect the different prototrophs, or combinations of genes in an individual, to be recovered with different frequencies according to the particular character used as a basis for selection, as this will alter not only the types of prototrophs but also the types of non-prototrophs and the ratio of prototrophs to non-prototrophs. It is significant in this respect that Newcombe and Nyholm[8] obtained different linkage relations for non-selected characters according to whether they selected the prototrophs for their ability to grow on a minimal medium or for particular streptomycin reactions of the recombinants.

Thus there is a large body of evidence suggesting that the type of suppression reported by Grigg occurs in these micro-organisms whenever prototrophs are selected in the presence of large numbers of non-prototrophs. Furthermore, this suppression appears to occur no matter whether the prototrophs are selected by their ability to grow on a particular minimal medium, or for their resistance to, or requirement of, a particular drug, their ability to tolerate poisons, or their resistance to a bacteriophage.

In fungi, linkage experiments depending on the complete analysis of tetrads, or asci, must be above suspicion of this particular type of disturbance; but mass analysis of sexual spores, such as ascospores, or conidia, by a series of screening media will open the way to upset by competitive suppression. Such disturbance is likely to be all the more serious when the prototrophs are rare, for example, when recombination between tightly linked genes is being investigated, for in these cases heavier inocula of spores are generally plated in order to secure a reasonable number of the rare recombinants.

The operation of competitive suppression of the type discussed above would make true linkage appear tighter than is actually the case, while genes which really recombine freely might appear linked.

The literature on the genetics of *E. coli* abounds with reports of anomalous segregations and apparent non-linear arrangements of genes. Since the linkage estimations are normally made by the recovery of prototrophs from inocula carrying 10^8 or 10^9 of each parental type of cell per ml., it may well be that they merely reflect the widespread occurrence of the Grigg phenomenon. Certainly until this point has been cleared up the observations cannot be taken as incompatible with a chromosome system of the conventional kind (though, of course, the justification for postulating such a system in bacteria is perhaps another matter); and the more complex the screening technique used for the analysis, the more involved the competitive systems and the more confusing the effects of suppression might be.

Should the Grigg phenomenon turn out to be a source of complication in such linkage experiments, it is not easy to see a simple way of avoiding its effects. To keep the spore concentration constant in any set of determinations is an obvious elaboration of the standard technique; but this could not be relied on to do more than stabilize the disturbance so that a correction, which must itself be obtained from other considerations, could be applied. The correction, or the spore concentration, might well, however, have to be varied between the experiments involving different genes, for there is evidence that non-prototrophs of different kinds may not show the same strength of suppression on the various prototrophic recombinants. The only sure way round the difficulty would be the possibly tedious and demanding method of always using concentrations at which suppression does not occur or at least is negligible.

I am indebted to Prof. K. Mather and Mr. A. Durrant for helpful discussion and criticism in the preparation of this paper, which was prepared while holding a research studentship from the Agricultural Research Council.

INTERNATIONAL HEALTH ORGANIZATIONS

By SIR ARTHUR MacNALTY, K.C.B.

PESTILENCE has ever been a stimulus to preventive medicine. The dire visitations of cholera in Great Britain led to Snow and Budd's discoveries that water conveyed the disease and later to Koch's discovery of the *Cholera vibrio*. As international communications increased, so did the risk of transmission of disease from country to country. The principles of collaboration between governments in matters of health, established by the first international conference in 1851, led to further international sanitary conferences, the first general convention on quarantine in 1903, and the founding of the first international health organization, the Office International d'Hygiène Publique, at Paris in 1907. The Office carried on the work of the former Constantinople Superior Board of Health in preventing the spread of cholera by Mahommedan pilgrims to the holy places of Arabia. It also supplied important epidemiological information and data to fifty countries and secured international agreement on many medical and public health problems.

In all this work, Great Britain, the pioneer in public health, often took the initiative and placed her experience and knowledge at the service of other countries. Nor, since the beginning of the century, has the United States been far behind in this respect. The Pan-American Sanitary Bureau was founded by an International American Conference in 1901, and the First Pan-American Sanitary Conference in 1902 organized its work. Under the able directorship (1920–46) of Surgeon-General Hugh S. Cumming, and, afterwards, under that of Dr. Fred L. Soper, the Bureau's activities expanded to cover all aspects of public health of concern to the American republics. From co-operating closely with the Paris office as an information bureau which promptly reported outbreaks of certain epidemic diseases of international importance, it has become a central health agency for all American countries, and, on request, renders such aid as is possible to these countries in the prevention, control and eradication of disease.

The first example of international collective action against epidemic disease was seen after the First World War. There were big epidemics of typhus fever and other diseases in Poland, Russia, Roumania, Greece and other parts of Europe, and the threat of their spread was a serious menace. Through the League of Nations National Council, in May 1920, the Epidemic Commission was set up, and its team of international experts helped the countries concerned to get the epidemics under control.

The Covenant of the League of Nations contained a mandate to the League "to endeavour to take steps in matters of international concern for the prevention and control of disease (Article 23 (f) of the Covenant)". The Health Organization of the League began in 1921, and its constitution was finally adopted by the fourth assembly of the League in 1924. Dr. L. Rajchman (Poland) held the post of medical director from 1921 to January 1939. Its Health Committee was composed of the chief national health administrations, including the United States. Its secretariat comprised a number of medical men of different nationalities, public health officers and assistant staff.

The Health Organization's work met with success. It established close relations beween the health services of different countries, gave information on public health questions and epidemics, promoted technical studies including international standardization, provided expert assistance in field investigations, organized study tours and set up a Far-Eastern Bureau in Singapore. The Organization was greatly helped by Sir George Buchanan, the British delegate to the Paris office and to all the International Sanitary Conferences during 1919–35, who recorded some of its achievements in his Milroy Lectures (1934); by Dr. M. T. Morgan, British delegate from 1936; by Prof. T. Madsen (Denmark), president of the Health Committee, 1921–37; by Prof. J. Parisot, president during 1937–47; and by many others.

During the Second World War co-operation on international health work was perforce restricted, and the Health Organization of the League of Nations was much reduced. When the War ended, in anticipation of threatened famine and severe epidemics, the United Nations Relief and Rehabilitation Administration was already in being. Though its duration was brief—it was dissolved in 1946—its labours controlled European epidemics, averted famine and supplied a temporary pressing need.

Following on the work of a technical preparatory committee which met in Paris during March–April 1946, a World Health Conference was held in New York in July of that year, attended by delegations from the fifty-one members of the United Nations, ten non-members, the Allied Control Commissions for Germany and Japan, and from ten international health organizations. As a result of this Conference, the World Health Organization was constituted and established. It has absorbed or integrated the work of previously existing international health organizations, set up its permanent headquarters at Geneva, and works in accord with the United Nations, the Food and Agriculture Organization, the United Nations Educational, Scientific and Cultural Organization, the International Labour Office and other important bodies. An interim commission made preparations during 1946–48 for the permanent World Health Organization, continued the statutory functions of the previous health organizations and conducted emergency health international work.

The objective of the World Health Organization is defined as "the attainment by all peoples of the highest possible level of health". For the time being, this high aim cannot be realized. Once more, international politics have placed obstacles in the way of world health. The U.S.S.R. and its satellites have withdrawn from the Organization, and the new government of China is not a member. With expenditure on armaments and national health services, there is little money available for helping and subsidizing the public health work of less progressive countries. The main work of the Organization seems, therefore, for the present to lie in epidemic intelligence, the making of international standards and the giving of expert advice, on request, to health administrations on public health matters. If disappointment be felt at this conclusion, when preventive medicine holds so many powerful weapons for the eradication of disease and suffering, it should be remembered that the work of the past hundred years has laid the foundations of international health, that much has been achieved, and that work of this character marks progress on the way to the time when all the nations of the world will unite for the good of mankind.

BRITISH WELDING RESEARCH ASSOCIATION

NEW FATIGUE TESTING LABORATORY AT ABINGTON, CAMBRIDGE

MUCH is already known of the fatigue properties of structural steel and other industrial metals, when tested as simple laboratory specimens. Even so, it is essential to take into account the geometrical and metallurgical notches introduced into structures by welding or other methods of fabrication if fatigue failures are to be avoided. Because of this, the fatigue testing of welded structural components forms an important part of the work of the British Welding Research Association at its Engineering Research Station at Abington, near Cambridge. This work has received new impetus with the completion of a new Fatigue Testing Laboratory, officially opened by Lord Woolton, Lord President of the Council, on June 23. The new laboratory, which has a floor area of 5,000 sq. ft., is of technical interest in itself, since it is the first building to be erected for which the plastic design method, originated by Prof. J. F. Baker, professor of mechanical sciences in the University of Cambridge, has been applied. Appreciable economies in steel have been effected thereby, and the architect and consulting engineers have been enabled to produce an æsthetically pleasing building in which the steelwork is particularly unobtrusive.

The structural components which are tested come from the oil and power, aeronautical, shipbuilding, automobile and general engineering fields, and it is not surprising, therefore, that three broadly different methods of load application are used. Of these, the method of resonance vibration has been used for some years. The basis of this is the Lanchester oscillator, in which a pair of eccentrically mounted masses are rotated in opposite directions by means of a variable-speed motor, to produce an oscillating force in a given plane relative to the specimen, which is freely suspended at its nodes. When the speed is adjusted to a point near resonance, considerable stresses are set up in the specimen. In one case, fatigue bending tests have been carried out on light box members simulating chassis members in a motor-car, while, at the other extreme, tension/compression loads of ± 30 tons have been excited in Bailey bridge members, by the addition of masses at either end to establish the correct mode of vibration. Precise control of the induced stresses is important, and is achieved by speed control, using either amplitude of vibration or strain, through a wire-resistance strain-gauge, as the variable governing the servomechanism.

The resonance method is flexible in its application to varieties of structure, but has the disadvantages of producing only equal tension and compression load-cycles, and a severe size limitation caused by the rate of wear of large oscillators. The Association has therefore acquired two non-resonating machines of 100 tons capacity for installation in the new laboratory. The Losenhausen machine, with mechanical and hydraulic actuation, works at speeds of 100–600 cycles per min. (compared with more than 3,000 cycles per min. for a resonance machine). An interesting feature is its mounting on twenty-four struts, the Euler crippling load of which has just been exceeded, so that they behave as soft springs, ensuring that no vibrations from the 20 tons mass of the machine are communicated to the foundation. This method of mounting was developed by T. S. Robertson, of the Naval Construction Research Establishment, Rosyth. The other machine was designed by Prof. W. M. Wilson, of the University of Illinois, and is operated by means of an eccentric and a load-multiplying lever. Two specimens may be tested independently and simultaneously in this machine, but only at 100 cycles per minute. Parts for this machine have been made in Great Britain and given to the Association by a number of manufacturers interested in furthering the work of fatigue testing. Both the Illinois and Losenhausen machines make provision for statically preloading the specimen during test, so that load-cycles to the extremes of zero to maximum tension or compression may be applied.

The remaining fatigue-testing machine operated by the Association is concerned with pressure vessels and pipeline components subjected to internal pressure. This consists of a large-capacity hydraulic pump, together with automatic valve gear designed to apply pressure pulsations from atmospheric to 6,000 lb./sq. in. at up to 100 cycles per min.

The method of fatigue testing is attractive, even for structural members which may not be subject to severe pulsating loads during service, because of the searching comparison which may be made between types of weld and methods of design. Proneness to failure through the effect of stress concentration is exposed where static loads would be sustained with full ductility.

In parallel with the full programme of fatigue testing at present being carried out by the staff of the laboratory, studies are being made of the mechanics of crack propagation, the phenomenon which is fundamental to brittle and fatigue structural failures.

A. A. WELLS

THE BEHAVIOUR OF BOWER-BIRDS

A COMMUNICATION by Prof. Evelyn Hutchinson, of Yale University, in a recent issue of the *American Scientist* (40, No. 1) throws considerable light upon the behaviour of bower-birds. The bower-birds are a group of Australian and New Guinea birds, generally classified along with the rifle-birds, Australian catbirds, and birds of paradise as the family Paradiseidæ, or pair of families, the Paradiseidæ and Ptilinorhynchidæ, which most ornithologists have regarded as closely allied to the crows. Though they lack the resplendent plumes of their allies, the birds of paradise, some of the bower-birds exhibit behaviour of a kind which in its complexity and refinement is unique in the non-human part of the animal kingdom.

The unique feature of the majority of bower-birds is that, during the breeding season, the males build tiny ceremonial houses, set neatly in clearings and furnished with a variety of objects which are used in display and which, when not in use, are piled up carefully on the cleared area in front of the bower. These bowers have nothing whatever to do with the nests of the species, which are constructed by the female alone at some little distance from the male's display area.

Hitherto this extraordinary type of behaviour has been interpreted anthropomorphically; but some recent papers permit the behaviour to be interpreted primarily in avian terms. The studies related mainly to two species, the tooth-billed bower-bird, *Scenopoeetes dentirostris* and the satin bower-bird, *Ptilinorhynchus violaceus*. The former makes no true bower, though its behaviour is remarkable enough, while the latter not only builds a bower but also paints the inside of it, and so is perhaps one of the most advanced and complicated of all bower-birds in its habits.

Scenopoeetes is found only in a restricted area of north-eastern Queensland, living in tropical rain-forest. It is a dull-coloured bird about 27 cm. long and exhibits no external sexual dimorphism. The most remarkable morphological feature of *Scenopoeetes* is a triple saw-toothed apex to the maxilla, which fits into depressions at the apex of the mandible.

Like so many other male birds, the male *Scenopoeetes* occupies a definite territory during the breeding season, and from that territory he calls or sings. The central part of the territory, under the singing perch, is defined as a clearing, all the litter of the tropical forest floor being carefully taken away. On this clearing or stage, every morning the male *Scenopoeetes* arranges a number of leaves sawn off from neighbouring bushes and trees and placed with the pale conspicuous lower surfaces uppermost. Before this is done, the withered leaves of the previous day are carefully removed to a refuse pile outside the stage. The leaves are gathered by sawing through the petiole with the toothed tip of the beak. Not all species of bush or tree produce leaves which suit the tastes of *Scenopoeetes*, and individual males appear to have individual tastes in this matter. The leaves of *Alpinia* and *Darlingia*, which are often used, may be twice as long as the bird which collects and arranges them. The stage, which may be up to 2 m. × 3 m. in dimensions, can have more than forty leaves laid out on it. Although the toothed apex of the bill is not known to have any function other than that of sawing through leaf petioles, many of the leaves used can be easily detached by a sharp pull that would seem to be well within the physical capabilities of the bird. If *Scenopoeetes* had discovered this, its whole life might have been easier, though its evolution would probably have run a different course.

In *Ptilinorhynchus violaceus* there is a more elaborate type of behaviour. The bird is about the same size as *Scenopoeetes* and of normal form, but is strongly sexually dimorphic; both sexes have intensely blue eyes. The males do not acquire their adult plumage until they are at least five years old. This is a remarkable age for maturity in a passerine bird, for most species have a mean expectation of life at fledging of a little over a year, and show little change in survivorship from year to year, even when the potential physiological longevity may be ten or a dozen years.

The bower of *Ptilinorhynchus* is described as made of two parallel rows of sticks, each row being about 30 cm. high and 35 cm. long. The two rows lean towards each other, so producing an incomplete roof space. The long axis of this structure is normally set north and south, and in front of the north end a display area is cleared.

On the display area, a number of coloured objects are systematically arranged. The objects collected by *Ptilinorhynchus* are usually blue, less often lemon-yellow or greyish-brown. Throughout the entire breeding season, the male is likely to pick up one of these objects, moving in and out of the bower and displaying in front of the object by erecting the feathers and making characteristic movements. A female may be lurking behind the bower while this is happening; but the male appears to pay more attention to the blue flowers, berries, pieces of broken glass, or in some cases even street-car tickets, than to the blue eyes of the female.

The bower, therefore, cannot be involved in sexual selection as such, though, since the building habits develop each year in association with increasing testicular activity, the bowers and adjacent display areas with the associated coloured objects presumably have a sexual significance. It is probable that the blue and to a less extent the other coloured objects provide a greatly enhanced visual stimulation of the kind otherwise received from the blue eyes and possible other epigamic colouring of the female.

After mating, the female leaves the area of the bower and builds a nest by herself. Throughout the period of nest building and incubation the male continues displaying at the bower. During this period spermatogenesis continues actively, though in most single-brooded monogamous birds sperm production stops after mating and nidification. When the young are fledged, they are brought by the female to the bower and for a week or two the family engage in communal display activities. Then the bower is abandoned and all birds join the autumnal feeding flocks.

Some males of *Ptilinorhynchus* have the extraordinary habit of making a paint out of charcoal, or fruit pulp, mixed with a secretion produced from the mouth, and of applying this paint to the inside of the bower by means of a wad of fibre from some soft kind of bark. The habit is exhibited only at the height of the breeding season, when spermatogenesis is most active and mating and ovulation are occurring. The significance of this behaviour is entirely unknown.

The available information suggests that the extraordinarily specialized behaviour of the bower-birds is an immensely complicated development of avian territorialism. The chronology of the events in relation to spermatogenesis, no less than the detailed sequence of the behaviour itself, is in accord with this idea. The need for such behaviour arises from the fact that it is advantageous for any male to secure his territory and mate as early as possible, for competition is often severe, while it may be highly disadvantageous for reproduction to begin until much later in the year when adequate food for the young is available.

In addition to an elaboration of this kind, there is the extraordinary substitution of inanimate objects for the primary sexual stimulus, a process which would be termed fetishism in human psychopathology. This curious development directs attention to the way in which individual culturally determined acts in man so frequently have parallels in the specifically characteristic behaviour of birds.

HEALTH OF THE SCHOOL CHILD

IN "The Health of the School Child", the report for 1948–49 of the Chief Medical Officer to the Ministry of Education (London : H.M.S.O., 1952. Pp. 92. 3s. net), it is stated that the children in Great Britain are healthier than ever before in our history.

The numbers of under-nourished school children are now so small that school medical officers do not consider that the subject calls for special mention. Some of them, however, give data on heights and weights. Between 1939 and 1949, London school children gained an average of ¾ in. in height and 1¾ lb. in weight. A striking feature was that the changes in height and weight were proportionate ; while the greatest improvement had been in districts above average in 1938, there had also been a definite improvement in the worst areas. Children were not merely taller and heavier than their parents but were members of a generation altogether of greater physique. Figures relating to 5-year-old children in Wolverhampton showed that girls gained an average of over 6¼ in. in height and more than 8 lb. in weight between 1909 and 1949 ; boys gained an average of nearly 4¼ in. and 6¼ lb. during the same period. Weighing machines in senior schools in this area were no longer adequate for pupils in their last year.

During the period 1939–49, the school meals service multiplied roughly seventeen times and had changed out of all recognition. With restrictions on the building of new canteens, the report suggests concentration on stabilizing and improving the existing service. The development of training courses for staffs at all levels is proposed. The lack of courses for women who serve the meals is unfortunate, particularly since reports on food poisoning frequently attributed the trouble to lack of knowledge in the canteens.

Figures for October 1949 showed that 53·2 per cent of the children present (2,851,000) took school dinners, and there were 23,000 canteens serving 27,000 schools. 1,950 schools were then without school meals facilities. In addition, 86·9 per cent (4¾ millions) of the children present took milk in school. More than 98 per cent of the milk was either tuberculin-tested or pasteurized.

During 1948, 96,262 school children had tonsil operations. The following year the figure fell to 69,449. The large number of operations in 1948—the figure was only exceeded in 1929–30–31—was mainly due to the widespread poliomyelitis epidemic in 1947. This caused the postponement of operations which would have been carried out in that year. The report stresses that tonsillectomy is scarcely ever an urgent operation and that only cases in need of urgent treatment should be referred to hospital for operative treatment. It is becoming increasingly realized that tonsillectomy is not a trivial operation and should not be treated lightly. Cases that are not urgent should be kept under observation for at least three months before being referred to a surgeon. All cases put on hospital lists should be examined periodically, since experience has shown that many who had been on a waiting list for a long time no longer required treatment. It is more important to deal safely and efficiently with a few children than to operate on large numbers, many of whom are in no need of urgent treatment.

The serious effect of the National Health Service on the school dental service is discussed. Because of the higher incomes obtainable under the new general dental service, many school dentists resigned to enter private practice. By the end of 1949, the number of school dental officers was 884 (equal to 732 full-time officers), compared with 1,063 (921 full-time) in 1947. In eighteen months, the service had lost one-fifth of its strength and was back to its war-time position.

There are signs in some areas that the improvement in the teeth of school children during and just after the War is on the wane. One report suggested that sticky buns given by mothers to restive young children was the possible cause of "the deplorable teeth so often seen in children between 5 7 years".

Nearly 450,000 school children (8 per cent of those on the registers) were found to be in a verminous condition in 1949. This was "profoundly disappointing" and showed no improvement on post-war years. In 1948, more than 4½ million school children—probably more than half of those on the registers—were medically examined or re-examined, other than for dental disease or verminous condition. The incidence figures for the various defects showed no major changes from those of 1947, though increases in the number of cases of defects of vision and speech needing treatment were recorded.

The new outlook on physical education is commented upon, and the growth of interest and skill in athletics noted. In Wales, athletics had made considerable headway where hitherto progress had been slow. The Midland and South-Western Divisions also reported an increase in the popularity of athletics ; in the North-Western Division it was "probably the one aspect of physical education in which improvement was most obvious".

The report contains a special chapter on the problems of diabetic children. England is believed to be the only country in the world providing hostels for these children ; but the report stresses that while such accommodation is indispensable for a minority of diabetic children, the great majority should remain at home since there was no substitute for a good home. The report also contains chapters on the co-ordination of the school health service with the National Health Service, the treatment of defective vision, and the prevention of tuberculosis in school children.

The cost of the school health service and special schools, which was £10,194,000 in 1947–48, fell to £9,234,000 in 1948–49.

INCENTIVES AND SIZE OF INDUSTRIAL PLANT IN GREAT BRITAIN

THE information about the "Proportion of Time-workers and Pieceworkers" which is published by the Ministry of Labour[1] may be expected to direct inquiries on industrial structure into new channels. A remarkable connexion between the distribution of pieceworkers and the variation of the size of plants emerges from this information, a connexion which in the past seems to have been overlooked by both theoretical and empirical studies in this field.

The first detailed survey of methods of wage payments in separate industries appeared in 1947; it was followed by two similar but more elaborate surveys, for October 1949 and October 1951. A new feature of these two is the classification of the data according to the size of industrial plants. Four size-classes are distinguished: establishments with less than 25, 25–99, 100–499, and with 500 or more wage-earners. Pieceworkers are defined as workers paid under any system of "payment by results", and data are supplied for 131 separate (mostly manufacturing) industries. The 1951 survey covers some 6¼ million workers, which amounts to more than two-thirds of the total number employed in the 131 industries.

To appreciate this material it should be recalled that the Census of Production gives data on size of plants and wages but not on wage methods. Although it might seem plausible that incentive schemes are more suitable for larger than for smaller plants, there has been no evidence of this. Indeed, it is known that they are widely used in such industries as cotton, potteries, dressmaking, etc., where relatively small and medium, rather than large, plants prevail. Thus, a close relationship between an industry's size-structure and particular payment methods could scarcely be expected. That it does exist, nevertheless, can now be seen from the Ministry of Labour surveys. We must exclude, of course, those industries where the proportion of pieceworkers as a whole is too small (say, less than 10 per cent) to be significant for the present purpose or where the information for separate size-classes is incomplete. There remain seventy-five industries, and forty-seven of these show a consistent relation between size-structure and incentives: the proportion of pieceworkers increases step by step with increasing size of plant. In iron and steel melting and rolling, for example, the percentage of pieceworkers rises from class I (less than 25 workers) to class IV (500 and more), in 1949, as follows: 25, 37, 51 and 65 per cent; and similarly in 1951: 24, 41, 54 and 66 per cent. Other important industries with the same pattern are motor-vehicles, rayon and nylon weaving, building, boots and shoes, rubber, furniture and iron foundries. The industries which do not show a connexion between size of plant and methods of payment include woollen and worsted, cotton weaving, tailoring and agricultural machinery.

While a full explanation must wait for further data, two conclusions may already be suggested. The specific advantages of larger organizations are not only a matter of technical conditions, but involve also the opportunity of controlling a relatively larger number of workers through wage incentives; and the possibility of increasing the use of incentives, on the other hand, depends at least partly on the scope for expansion. There can be no doubt that the Ministry of Labour surveys are extremely useful for the advancement of research into these problems. It would be desirable, however, if in future actual figures of wage-earners, not merely percentages, could be supplied, and if the largest size-class could be split up into 500–999 and 1,000 and more workers. It would then be possible to link up the information with the Census of Production. W. BALDAMUS

EAST AFRICAN INDUSTRIAL RESEARCH BOARD

REPORT FOR 1951

THE ninth annual report of the East African Industrial Research Board* covers activities for the year ending December 31, 1951. Laboratory trials described in the last annual report have been followed by an experimental run at a factory producing sodium phosphate commercially, which has demonstrated that a satisfactory product can be obtained in a continuous chamber kiln fired by wood producer-gas, with proper control of firing. Storage trials over a period of three months have demonstrated that there is no deterioration of this type of product, provided there is no marked leaching.

The characteristics of cement clinker obtained by burning varying proportions of a product containing less than 0·5 per cent of phosphorus pentoxide, from limestone containing 2 per cent of phosphorus pentoxide, with raw limestone and clay are being investigated, and also the effect on refractory quality of bonding different grain-sizes of kyanite with various materials. Two new clay deposits have been found which proved satisfactory bond clays for refractories, and certain lavas have been found which can form the basis of a glaze for drain-pipes and which can be fired at a lower temperature than that required for salt glazing. The distillation of surplus wood from the wattle industry to give charcoal and wood tar is being investigated, and metallurgical charcoal obtained from wattle may be of use for smelting and other purposes in the Tororo area. Simple pulverization reduced the bulk density of the husk from dried coffee cherry sufficiently to permit its transportation for use as a substitute for bran in stock feeds. Mixed fatty acids obtained from the seeds of *Moringa oleifera* are highly suitable for froth flotation in the production of kyanite, and a drying oil which is satisfactory for paint manufacture has been obtained in 17 per cent yield from the whole nuts of *Aleurites triloba*, grown in Uganda, and in 55 per cent yield from the kernels.

Hecogenin, a steroid, which can be used as a raw material for the synthesis of cortisone, can be conveniently obtained from the juice of the sisal leaf, and a pilot plant has been built at the laboratory to provide the Medical Research Council with a supply of hecogenin for the synthesis of cortisone. A note appended to the report outlines the process and indicates the work which an officer of the National Institute for Medical Research is carrying out on the occurrence of hecogenin in sisal leaves. A note on the drying of sisal fibre and a list of publications on industrial research are also appended.

Evidence for the Polarization of the Protons produced in the D—D Reaction

SEVERAL authors[1,2] have measured the angular distribution of the particles produced in the D—D reaction as a function of bombarding energy in the range 100–400 keV. A theoretical fit to the observations demonstrates the possibility of a strong spin-orbit coupling in the interaction[3]. This coupling may produce polarization of the outgoing protons[4]. The polarization can be detected by observing the azimuthal angular distribution of D—D particles scattered by nuclei in a process involving spin-orbit coupling. An azimuthal anisotropy would be proof of the polarization. Such an anisotropy has been demonstrated in a double-scattering experiment for protons of 3-meV. energy scattered by helium[5]. This provides a valuable analyser for the polarized proton. It was therefore decided to use this method in the search for a polarization of the protons produced in the D—D reaction. A previous attempt to detect polarization of the neutrons by scattering on carbon was vitiated by the background of neutrons produced by scattered deuterons in the accelerator tube.

A beam of 300-kV. deuterons was collimated by two diaphragms of 5-mm. diameter on to a heavy-ice target, thus producing 10^8 protons per second. Protons escaping at an angle of 120° to the deuteron beam were allowed to go through an aluminium window 6·5 mgm./cm.^{2}, and to pass through a scattering chamber (1·2 cm. diameter) containing helium at atmospheric pressure. The scattered protons were detected with a proportional counter (diameter 2 cm., length 7 cm.), filled to a pressure of one atmosphere with argon, at a distance of 2 cm. from the axis of the scattering volume, separated by an aluminium window (2·8 mgm./cm.^{2}). Protons that had passed through an average of 4·0 cm. of helium and which were scattered through an angular range (75°–120° centre of mass) could enter the counter. At the moment of being scattered they had an energy of (2 ± 0·2) MeV. Their energy on entering the counter was 600 keV., which is more than twice the maximum energy of argon recoils from the 2·5-MeV. neutrons. The walls of the counter were lined with lead in order to avoid a background of protons due to an (n,p) reaction which a brass wall counter was found to give.

The whole arrangement of scattering volume and counter could be rotated around the axis of the scattering chamber.

The centre of the scattering volume was 7·5 cm. from the target, which was aligned at 60° to the deuteron beam. The copper target was cooled with liquid air, and heavy ice was formed on it continuously. The size of the copper target was such that displacements of the incident deuteron beam could not cause serious asymmetries in the intensity of the proton beam in the scattering chamber. The measurements were monitored with a neutron recoil counter (filled with methane at 20 atmospheres pressure). The ratio of the intensity of scattered protons to neutron monitor counts was found to be constant within the statistical accuracy of 5 per cent, for any one orientation of the scattering chamber. The proton counting-rate was measured forward and backward in the plane of incident deuteron and emitted proton beams, and in the two positions normal to this plane. The rates observed were

Forward	1·80 ± 0·07
Backward	2·97 ± 0·11
Normal positions	2·30 ± 0·08, 2·3 ± 0·09

The azimuthal distribution is of the form $\sigma(\theta,\varphi) = \sigma[1 + PA \cos\varphi)$, where φ is the angle between the normals to the scattering planes. The magnitude of A is estimated from the geometry of this experiment and an average value for the analyser efficiency[5] of 87 per cent obtained. The product PA is evaluated from the above data and equation, correcting for the range of φ accepted by the counter. The value of PA is 0·25 ± 0·05. The analyser efficiency A is 0·87 for our geometry, with an uncertainty due to the experimental errors on the data obtained for p—He scattering. Thus the polarization of the D—D protons is (30 ± 6) per cent.

The symmetry of the D—D reaction for proton and neutron emission leads one to expect a similar degree of neutron polarization. Longley, Little and Slye[6] have reported a polarization of (40 ± 20) per cent for D—D neutrons. We cannot make a comparison with our result since they do not indicate the energy of their deuteron beam.

The interest of the availability of a source of polarized neutrons and protons for the investigation of spin-orbit coupling in nuclear scattering and of the interaction of polarized particles with polarized nuclei is obvious.

We are much obliged to Dr. R. J. Blin-Stoyle for suggesting this experiment to us, and for many stimulating discussions. We thank Lord Cherwell for his continued interest. One of us is indebted to Imperial Chemical Industries, Ltd., for a research fellowship, and another to the Department of Scientific and Industrial Research for a maintenance grant.

Weak Echoes from the Ionosphere with Radio Waves of Frequency 1·42 Mc./s.

IT is well known that medium-frequency radio waves (0·5–1·5 Mc./s.) are often very highly absorbed in their passage through the lower ionosphere, so that the amplitude of the echo may fall below the limit of detectability of the usual ionospheric recording equipment. The occasions of greatest absorption occur in the day-time in summer, on certain days of abnormally great absorption in winter and for short intervals during radio fade-outs.

By the use of a new method, we have been able to improve the sensitivity very considerably and have been able to make measurements throughout days of high absorption in winter on a frequency of 1·42 Mc./s. It is the purpose of this communication to outline the results obtained. The apparatus will be described in detail elsewhere. It is sufficient to state here that it uses a frequency-modulation method, which is a development of the original Appleton and Barrett frequency-change technique, and that special arrangements are made to integrate the output over a period of the order of 1 sec.

As in all 'radar' systems, the ultimate sensitivity depends on the mean power of the sender, provided the receiver is designed for optimum signal-to-noise ratio. With a pulse system the optimum signal-to-noise ratio could only be achieved by the use of pre-detector integration; it is not achieved with the ordinary type of pulse receiver. A comparison of our new system and the ordinary kind of pulse system may be made by stating that our mean power is 500 watts and our effective receiver band-width 1 c./s., whereas a typical high-power pulse apparatus uses a mean power of 100 watts (peak power 10 kw., pulse-width 200 sec., repetition frequency 50 c./s.) with a band-width of 20 kc./s.

It is easily possible with our apparatus in its present form to detect echoes corresponding to reflexion coefficients of 3 × 10^{-5} (attenuation 10 nepers).

Experiments on a frequency of 1·42 Mc./s. have been in progress since the beginning of the year. On several days of high absorption in January and February, when our colleagues, working with a pulse sender of frequency 2 Mc./s. and a peak power output 1 kw., were unable to detect any echo, waves of frequency 1·42 Mc./s. were observed to be reflected from heights between 75 km. and 80 km., and the effective reflexion coefficient was found by measurement to be less than 3 × 10^{-4}. On other days when the absorption was less, there were discrete reflexion heights near 90, 96 and 112 km., the latter height corresponding to the ordinary *E* region observed by our colleagues on a frequency of 2 Mc./s. These reflexion levels (75–80 km., 90–95 km. and 112 km.) appear to be the same as those observed by Naismith and Bramley[1] in measurements with waves of frequency 2 Mc./s. at oblique incidence. Since mid-March, the reflexion height has been consistently in the range 102–105 km., corresponding closely to the ordinary *E*-region reflexion. This height is still observed if the sender frequency is reduced to 1·025 Mc./s., so that there cannot be, at this time of year, any lower layer with electron density greater than about 1·3 × 10^{4} cm.$^{-3}$.

Fine Structure of Chloroplasts in Two Flagellates

THE structure of chloroplasts has been described in several recent reviews[1]. Previous information based on the use of the polarizing[2], ultra-violet[3] and electron microscopes[4] has provided some evidence that the chloroplasts have a lamellar structure. The electron microscope studies have been made exclusively on isolated plastids in which artefacts may be easily produced by disintegration and injury during the preparation of the specimens. The electron micrographs obtained have shown that the chloroplasts and even the grana consist of disks; but they have not yielded information about the orientation of these disks to one another. Progress in embedding and thin-sectioning techniques now permits us to examine in the electron microscope the structure of intact chloroplasts *in situ*. The present communication summarizes observations made by such methods on the chloroplasts of two algal flagellates, *Euglena gracilis bacillaris* and *Poteriochromonas stipitata* (a phagotrophic chrysomonad).

These flagellates were grown in chemically defined media[5] in light and in darkness. In light, they were deeply pigmented; in darkness they became completely colourless; this process was reversible. In the present study, in which they were grown under continuous light for four to seven days, both species contained elongated chloroplasts (1–2 μ in diameter and 5–10 μ in length for *Euglena*, smaller ones for the chrysomonad) which appeared faintly laminated in the phase-contrast microscope. For electron microscopy the flagellates were fixed in 1 per cent osmium tetroxide in 0·028 *M* acetate-veronal buffer, or in 0·21 *M* sucrose, embedded in *n*-butyl methacrylate, and sectioned at 0·05 μ (see ref. 6 for detailed techniques).

The electron micrographs of the sections of *Euglena* (Fig. 1) show that each chloroplast is approximately 1 μ in thickness, is limited by a membrane, and consists of a number (approximately twenty) of regularly oriented lamellæ. In cross-sections (Figs. 2 and 3) the lamellæ can be seen as dense bands, nearly uniform in thickness, and appearing to be continuous and homogeneous at the resolutions used. Measurements on fifty of these bands gave an average thickness of 250 A. (variations from 180 A. to 320 A.). The interlamellar spaces vary in thickness from 300 A. to 500 A. and contain a less-dense material that appears homogeneous except for occasional dense granules of 300–800 A. in diameter. Since there was no control on the angle of cutting, chloroplasts were frequently sectioned on the bias. Consequently, in such sections both the lamellæ and the interlamellar spaces show increased thickness. For this reason it is believed that the smallest values found for the thickness of the lamellæ are the more reliable. Additional factors appear to play a part in the variability of the spacing of the lamellæ; in poorly fixed material, they are frequently pulled apart and sometimes fractured. The most regular layering was found in material fixed by 1 per cent osmic acid in 0·21 *M* sucrose. A certain variability in the spacing of the lamellæ may indeed be present *in vivo* and explain the faint lamination seen in the phase-contrast microscope; obviously the lamellæ them-

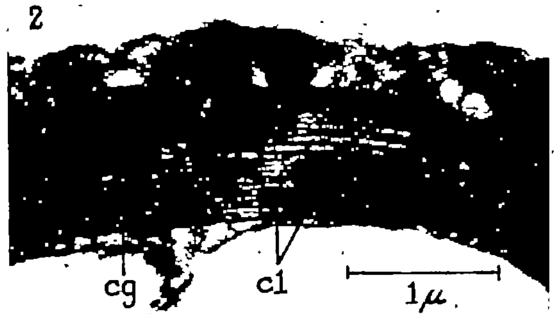

Fig. 2. Section through a chloroplast showing lamellæ (cl), interlamellar spaces and some chloroplast granules (cg). × 20,000
Fig. 3. Section through a chloroplast showing the pyrenoid (py). × 15,000

selves are below the limit of resolution of this instrument. Since the size of the chlorophyll molecule is below the limit of resolution of the electron microscope, nothing can be said at present about the location of chlorophyll in respect to the lamellæ.

A dense body found in the centre of the chloroplasts in some of our electron micrographs is interpreted as the pyrenoid; it appears as a condensation of interlamellar material, with which it is frequently continuous. The lamellæ can be followed, in some cases, through the pyrenoid and appear to be tightly held together in this region (Fig. 3). In other instances, namely, in very dense pyrenoids, the lamellar structure seems to disappear at this level. A large cytoplasmic vacuole is frequently present outside the chloroplast in contact with the pyrenoid.

Chloroplasts with structure and organization similar to those of *Euglena* were found in *P. stipitata.* Further studies on the light versus dark reaction in the formation and structure of the chloroplasts are in progress; a full account of this work will be reported and published elsewhere[7].

Screw Dislocations in Quartz

In a recent letter in *Nature*, Amelinckx[1] has given evidence for the existence of screw dislocations in mica. He observed a step, 140 A. high, which terminated on the surface: the point of termination of the step defined the point of emergence of a screw dislocation of Burgers's vector 140 A.

I have obtained similar evidence for the existence of screw dislocations in quartz. Fig. 1 is a photograph of the major rhombohedral face $(10\bar{1}1)$ of a natural quartz crystal, showing the edges of growth sheets which have spread in two separate directions, denoted α and β in the figure. The α growth fronts are continuous, and parallel to the geographical contours of the face; but the β growth fronts are discontinuous along the diagonal black line. This line is terminated on the surface at both ends, and is parallel to the line of intersection of the face with an adjacent major rhombohedral plane. Fig. 2 is the corresponding two-beam interference picture (λ = 5460 A.) of the area shown in Fig. 1, and shows that the diagonal line represents a step the height of which varies between 0 and 950 A.

It is well known[2] that the $\{10\bar{1}1\}$ major rhombohedral planes of quartz are planes of 'partial cleavage'. We can conclude that the diagonal line in Fig. 1 is a slip line, partial slip having taken place parallel to the major rhombohedral plane. The points of termination of the slip line, and the points along its length where a change of height occurs, mark the points of emergence of screw dislocations.

The slip line in Fig. 1 is much more visible than the growth fronts, although the latter are approximately 3000 A. high—that is, several times higher than the maximum height of the slip step. The reason for this reduced visibility of the growth fronts is that the risers of the growth fronts make a small angle (approximately 1°) with the plane surface of the growth sheets, whereas the slip line represents a sharp, vertical step.

I have observed a growth spiral on quartz, indicating that growth had taken place from a screw dislocation of Burgers's vector 220 A. This is therefore additional evidence for the existence of dislocations in the quartz lattice. It is hoped to publish a fuller account of a study of the topography of quartz surfaces elsewhere.

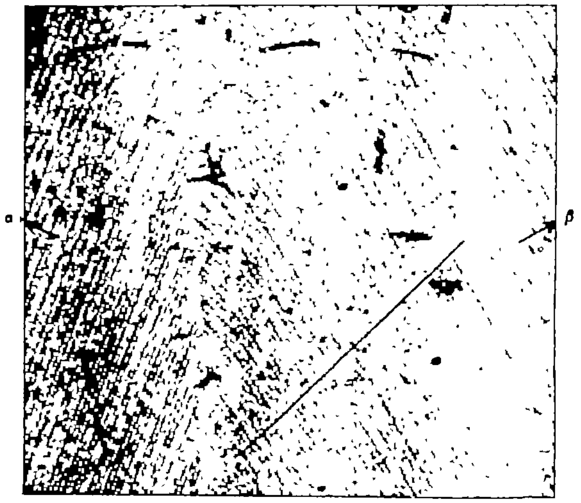

Fig. 1. (× 7)

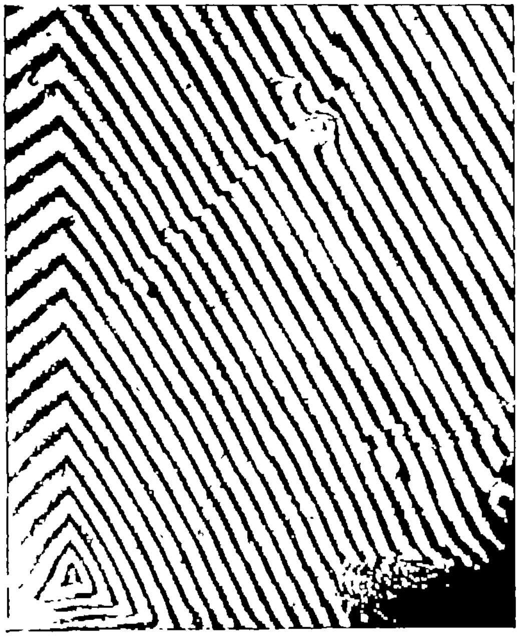

Fig. 2. (× 7)

I wish to thank Prof. S. Tolansky for his continual interest in this work; the Director, Signals Research and Development Establishment, Christchurch, for the loan of the crystal; and the Chief Scientist, Ministry of Supply, for permission to publish this account.

The Energy Momentum Tensor in Dirac's New Electromagnetic Theory

DIRAC has recently[1] proposed a generalization of his new theory of electromagnetism so as to permit vortical streams of the electrical charge. The vortical motion has been introduced by redefining the potentials in a more general manner. Dirac has then framed two stationary principles, both of which lead back to the Lorentz equation of motion for an electric charge, with, however, the ratio, $m/e = k$, only occurring in it. The first of these stationary principles has for its action density

$$L = -\tfrac{1}{4}F_{\mu\nu}F_{\mu\nu} + \tfrac{1}{2}\lambda\,(v_\nu v_\nu - 1), \tag{1}$$

where the potentials are assumed to be of the form

$$A_\mu = kv_\mu + \xi\frac{\partial\eta}{\partial x_\mu}. \tag{2}$$

In these equations v_μ is the velocity vector, $v_\mu v_\mu = 1$, and ξ and η are two independent functions of the x_ν. λ is an arbitrary function of the x_ν. Varying the integral Lagrangian (1), one gets the equations,

$$v_\nu v_\nu = 1, \tag{3}$$

$$k\,\frac{\partial F_{\mu\nu}}{\partial x_\nu} = \lambda v_\mu \tag{4}$$

and

$$\frac{\partial F_{\mu\nu}}{\partial x_\nu}\,\frac{\partial\xi}{\partial x_\mu} = \frac{\partial F_{\mu\nu}}{\partial x_\nu}\,\frac{\partial\eta}{\partial x_\mu} = 0, \tag{5}$$

so that

$$v_\mu\,\frac{\partial\xi}{\partial x_\mu} = v_\mu\,\frac{\partial\eta}{\partial x_\mu} = 0. \tag{6}$$

(4) is the Maxwell equation, and (5) after reduction becomes the Lorentz equation

$$k\,\frac{dv_\mu}{ds} = v_\nu F_{\nu\mu}. \tag{7}$$

In making the variation, the A_μ, ξ, η and λ were treated as the independent field functions.

The canonical energy momentum tensor $T_{\rho\sigma}$ derived in the standard way from the Lagrangian (1) is

$$T_{\rho\sigma} = \frac{\partial kv_\lambda}{\partial x_\sigma}F_{\rho\lambda} + \frac{\partial\xi}{\partial x_\sigma}F_{\rho\nu}\frac{\partial\eta}{\partial x_\nu} + \frac{\partial\eta}{\partial x_\sigma}F_{\mu\rho}\frac{\partial\xi}{\partial x_\mu} + \delta_{\rho\sigma}L. \tag{8}$$

This tensor is not symmetrical and so with it angular momentum would not be conserved. To make it symmetrical we may proceed in the usual way (see, for example, Wentzel, "Quantum Theory of Fields", Appendix by Jauch) and add,

$$T'_{\rho\sigma} = -\frac{\partial}{\partial x_\lambda}\,(kv_\sigma F_{\rho\lambda}) = -\frac{\partial}{\partial x_\lambda}\,G_{\rho\lambda\sigma}$$
$$= \frac{\partial}{\partial x_\lambda}\,G_{\lambda\rho\sigma}. \tag{9}$$

$T'_{\rho\sigma}$ has the necessary properties of vanishing divergence and vanishing integrals of the energy and momentum components, for

$$\frac{\partial T'_{\rho\sigma}}{\partial x_\rho} = -\frac{\partial}{\partial x_\rho}\,\frac{\partial}{x_\lambda}\,G_{\rho\lambda\sigma} = 0,$$

$$\int T'_{4\sigma}\,dx_1dx_2dx_3 = -\int\frac{\partial}{\partial x_\lambda}\,G_{4\lambda\sigma}\,dx_1dx_2dx_3$$

$$= -\int\frac{\partial}{\partial x_k}\,G_{4k\sigma}\,dx_1dx_2dx_3 = 0.$$

Now by (4),

$$T'_{\rho\sigma} = -\frac{\partial kv_\sigma}{\partial x_\lambda}F_{\rho\lambda} - kv_\sigma\frac{\partial F_{\rho\lambda}}{\partial x_\lambda} = \frac{\partial kv_\sigma}{\partial x_\lambda}F_{\rho\lambda} - v_\sigma\lambda v_\rho. \tag{10}$$

So the symmetrical tensor, $\theta_{\rho\sigma} = \theta_{\sigma\rho}$, is

$$\theta_{\rho\sigma} = T_{\rho\sigma} + T'_{\rho\sigma} = F_{\sigma\lambda}F_{\rho\lambda} - v_\sigma\lambda v_\rho + \delta_{\rho\sigma}L. \tag{11}$$

The ξ and η variables do not appear explicitly in this formula, and the tensor is, apart from notation, of the same form as the tensor of the irrotational theory, the θ_{44} and θ_{4k} components of which have been given by Le Couteur[2].

I thank Prof. P. A. M. Dirac for suggesting this problem to me.

Calculation of the Internal Surface of a Lung

The following investigation arose out of work carried on in the Pathology Department of King's College, University of Durham, by Prof. J. B. Duguid and his colleagues, for which an estimate was needed of the respiratory surface area within a given volume of lung.

Tomkeieff[1] showed that, in a convex three-dimensional figure, the average linear intercept is equal to four times the volume divided by the surface area; that is,

$$\bar{l} = 4 \times \frac{\text{Volume}}{\text{Surface area}}.$$

If a number of similar such bodies, each of volume v and surface area A, are enclosed at random in a unit volume (V) and this volume is traversed by a number of lines of total length T, if also L is the total length of these lines which is interior to the convex bodies, and N is the number of intercepts, then

$$\frac{L}{T} \rightarrow \frac{\text{Volume of convex bodies}}{\text{Unit volume}} = \frac{L}{4NV} \times \Sigma(A),$$

and in the limit

$$\frac{\Sigma(A)}{V} = 4\,\frac{N}{T}.$$

Therefore, in the limit, the surface area per unit volume is equal to four times the number of intercepts divided by the total length of traverse.

It can further be shown that there is no necessity for imposing the restriction that the bodies should be similar to one another, or that they should be entirely enclosed in the unit volume. It is necessary, however, to postulate that the bodies should be randomly disposed towards the lines of traverse.

In the case of the internal surface area of a sample of a lung, the lung can be embedded in gelatine without shrinkage or distortion and cut in thin sections. These sections can then be scanned under a microscope, and all that is necessary to obtain the internal surface area is to count the number of intersections with cell walls that are made by the line of scanning and divide this number by two to give the number of intercepts. This scanning and counting can, in fact, be done electronically.

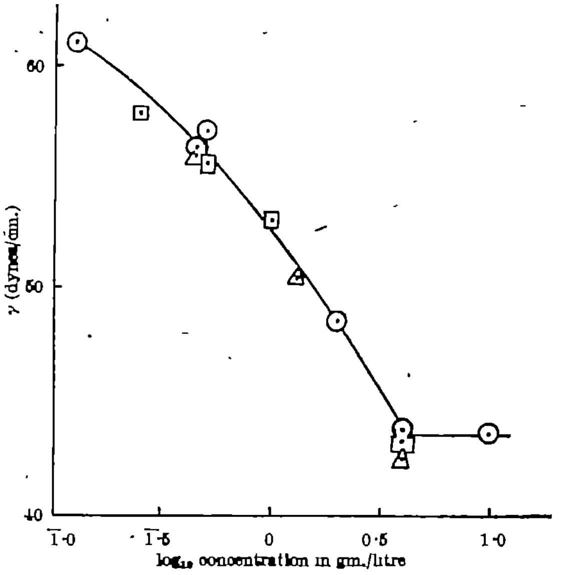
Hæmolytic and Surface Activity of Sodium Taurocholate

It is generally accepted that sodium taurocholate is a good lytic agent for erythrocytes, and a great number of reports on hæmolysis by this substance have been published[1]. Abnormal sigmoid time-dilution curves are sometimes reported for taurocholate lysis, and frequent reference is made to the instability of the taurocholate solutions used by these authors. One report[2] states qualitatively that a synthetic specimen of taurocholate was "moderately lytic", whereas a specimen prepared from natural sources was "strongly lytic". Two other reports[3] also give a much lower hæmolytic activity for taurocholate than that generally accepted.



γ – log *c* relation of sodium taurocholate in isotonic sodium chloride + boric acid buffer (0·02 *M*).
Line drawn as for *p*H 7, 20° C. ○, *p*H 7·0, 20° C.; ⊡, *p*H 7·0, 37° C.; △, *p*H 9·5, 37° C.

Through the generosity of Dr. Stenhagen, we have recently obtained a very pure specimen of sodium taurocholate, which has been examined for its hæmolytic and surface activity. Hæmolysis tests were made at 20° C. with a 5 per cent suspension of thrice-washed human erythrocytes (*AB*,*Rh*+) in 0·85 per cent sodium chloride buffered with 0·02 *M* boric acid, with borax added to *p*H 7·0. No lysis at all was observed overnight in concentrations of taurocholate up to 2·0 gm./lit. A solution of 11·0 gm./lit. effected complete lysis in approximately 30 hr., and one of 19·8 gm./lit. in 90 min. The lytic threshold for pure sodium taurocholate is therefore about 20 gm./lit. at 20° C. The values for human cells given in the papers already quoted are in the range of 0·10–0·15 gm./lit. for the lytic threshold. It is concluded that the previously accepted high lytic activity of sodium taurocholate is to be ascribed to the presence of impurities, perhaps long-chain fatty acids. The low activity of pure taurocholate has been confirmed by further experiments showing that a sample of natural taurocholate purified chromatographically and generously supplied by Dr. Pever has no lytic activity up to 3 gm./lit.

Determinations of surface tension were made at *p*H 7·0 and *p*H 9·5, and at 20° C. and 37° C. on solutions of Dr. Stenhagen's sample in the isotonic saline boric acid buffers described above. The Harkins drop-volume method was used in these determinations, with a glass-tipped tuberculin syringe operated by a micrometer screw. No decomposition of the test solutions was observed at room temperature, and in agreement with the opinion of Hutchinson[4], no surface tension ageing of the bile salt solutions was observed with this pure specimen. The results are given on a logarithmic concentration scale in the accompanying graph. The micelle point of the sodium taurocholate is 4·1 gm./lit. (7·4 × 10^{-3} *M*) in this medium and the maximum micellar surface pressure is 29·3 dynes. A full report will be published elsewhere to show that solutions of surface-active substances interacting weakly or not at all with cholesterol monolayers will lyse red cells strongly if their pressures are greater than 34 dynes. The strong hæmolytic activity previously reported for sodium taurocholate can now be ascribed to the lowering of the surface tension of solutions of the substance by surface-active impurities. The sigmoid time-dilution curves occasionally reported are interpreted as being caused by the zone of minimum surface tension produced by such impurities in solutions of micelle-forming surface-active substances[5].

Flattening of Meniscus between Water and Organic Solvents

WE have recently been carrying out experiments on the diffusion of solutes across the interface between water and organic solvents, using an optical method. In a cylindrical glass cell (2·4 cm. diameter) the meniscus is about 0·7 cm. deep, convex towards the water. This curvature would complicate the interpretation of diffusion measurements and would give a region on the organic solvent side where beams of light could not pass through undisturbed. If the tube is greasy, the meniscus is inverted.

It has been found possible to flatten this interface by a preliminary exposure of the inside of the tube to the vapours of 'Teddol', a preparation of the type Me_3SiF, which is strongly adsorbed on to the glass. A complete film would render the surface hydrophobic and give an inverted meniscus; but a suitably limited application gives a contact angle of 90°. In practice, it has been found more convenient to give a thorough treatment with 'Teddol' and then partially remove the film with a household metal polish on a test-tube brush. At intervals during the polishing the type of meniscus can be observed, until it is practically plane. When the interface is then formed, a very slight pressure on the liquid on one side or the other allows the final fine adjustment to a plane. With this technique it has been possible to cut down the gap in the light transmitted across the cell to less than 0·1 mm.

The surface formed is reasonably permanent, for the tube only needs re-treating at intervals of several months. It was shown that the optical properties of the tube were unaffected.

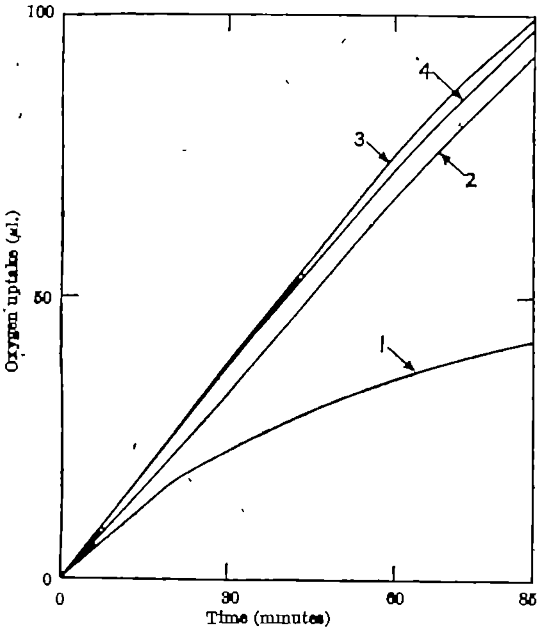
Stabilization of Oxidative Phosphorylation in Heart-Muscle Sarcosomes

FRESHLY prepared suspensions of the granular components of heart-muscle (sarcosomes[1], interstitial granules[2] or mitochondria[3]) are able to oxidize a number of intermediary metabolites, and to couple this oxidation with the synthesis of adenosine triphosphate from adenosine diphosphate and inorganic phosphate (oxidative phosphorylation)[4,5]. In agreement with the experience of other workers using preparations from different tissues, it has been found that the heart-muscle sarcosomes rapidly lose their ability to carry out oxidative phosphorylation, especially at temperatures above 0° C. Such aged preparations oxidize succinate at practically unimpaired rate, but the accompanying phosphorylation is lost. The ability to oxidize α-ketoglutarate is lost to about the same extent as the phosphorylation associated with this oxidation, so that the P : O ratio (the number of atoms of inorganic phosphate esterified per atom of oxygen consumed) is not greatly affected. The lability of rat heart sarcosomes is indicated by the following percentages of inactivation of the α-ketoglutaric oxidase system (the enzyme complex required for the aerobic oxidation of α-ketoglutarate to succinate): 10 min. standing at 15·5° C., 52 per cent inactivation; 15 min. at 25° C., 94 per cent inactivation. Cat preparations are somewhat more stable (15 min. standing at 25° C., 71 per cent inactivation).

These measurements were carried out with granules washed with isotonic phosphate-saline (0·135 *M* potassium chloride, 0·02 *M* phosphate, *p*H 7·4) and suspended in the same medium without further addition. The α-ketoglutaric oxidase system is much more stable in the presence of the reaction mixture used in oxidative phosphorylation experiments, the composition of which is given in the description to the accompanying graph. With cat heart sarcosomes, oxygen uptake and phosphorylation are maintained, under these conditions, at a uniform rate for 30 min. at 25° C.[5]. With rat heart preparations, on the other hand, the rate of oxygen uptake markedly declined after 15–20 min (see curve 1 of accompanying graph).

Since calcium is known to have a destructive effect on the morphology of sea urchin granules[6] and has also been shown to inhibit oxidative phosphorylation[7], the effect of the calcium-chelating agent, ethylenediaminetetracetate[8] (versene), was tried. Versene was found to protect, to a marked degree, the sarcosomal preparations from the morphological changes which occurred on standing. The accompanying graph (curves 2–4) shows that, in concentrations between 10^{-4} *M* and 2×10^{-3} *M*, it completely prevented the loss of activity of the α-ketoglutaric oxidase system which occurred with rat heart preparations even in the presence of the reaction mixture.

Versene, in higher concentrations, has an even more striking effect if it is added to the sarcosomal suspension during a preliminary incubation period before the preparation is added to the reaction mixture. For example, rat sarcosomes incubated for 15 min. at 25° C. in the absence of versene oxidized α-ketoglutarate at only 6 per cent of the rate of a control not given any preliminary incubation; both preparations were added to a reaction mixture containing 0·002 *M* versene. After incubation under the same conditions in the presence of 0·01 *M* versene, the preparation oxidized α-ketoglutarate at a rate



Effect of added versene on the oxidation of α-ketoglutarate by rat heart sarcosomes. Oxygen uptake measured manometrically in micro-flasks. All flasks contained, in a total volume of 1 ml., phosphate buffer, 0·036 *M*; potassium chloride, 0·026 *M*; sodium fluoride, 0·04 *M*; sodium malonate, 0·0089 *M*; glucose, 0·0167 *M*; adenosine monophosphate, 6×10^{-4} *M*; adenosine diphosphate, $6·7 \times 10^{-4}$ *M*; cytochrome *c*, $3·7 \times 10^{-6}$ *M*; magnesium, 0·005 *M*; α-ketoglutarate, 0·0074 *M*; sarcosomal preparation (1·4 mgm. protein) and hexokinase. *p*H 7·4, temperature, 25° C. Curve 1, no versene; curve 2, 10^{-4} *M* versene; curve 3, 10^{-3} *M* versene; curve 4, 2×10^{-3} *M* versene. The sarcosomal preparation was added at zero time without previous incubation

equal to 109 per cent of the control. In a similar experiment using sarcosomes isolated from cat heart and a 30-min. incubation period, 91 per cent inactivation was found after incubation in the absence of versene and 8 per cent activation when 0·01 *M* versene was added prior to incubation. The activity of the α-ketoglutaric oxidase system of cat heart sarcosomes, isolated with and suspended in isotonic phosphate-chloride containing 0·01 *M* versene, was unchanged after one day at 0° C., whereas that of a similar preparation isolated without versene was lowered by 84 per cent. At the end of this period, nearly all the sarcosomes in the latter preparation showed morphological changes, while no change had occurred in the preparation made with versene. Oxidative phosphorylation associated with the oxidation of α-ketoglutarate and succinate were also protected by 0·01 *M* versene; 0·001 *M* versene also gave considerable, although incomplete, protection.

EFFECT OF CALCIUM CHLORIDE ON THE INACTIVATION OF α-KETOGLUTARIC OXIDASE SYSTEM BY INCUBATION

Exp.	Preparation	Incubation		Conc. of calcium chloride added (*M*)	Inactivation (per cent)
		Time (min.)	Temperature (° C.)		
1	Washed versene	15	25	0	18
				0·000033	4
				0·000067	38
				0·0002	53
				0·00067	58
				0·0067	79
2	Washed versene	15	25	0	27
				0·001	72
				0·01	84
		5	17	0	11
				0·01	56
3	Normal	5	15	0	18
				0·001	37
				0·01	44

Since the reaction mixture contained 0·001–0·002 *M* versene in all cases (see graph), it is clear that although versene protects the enzyme systems from the inactivation caused by the incubation, it does not reverse such inactivation.

When the sarcosomes were isolated with an isotonic solution containing 0·01 *M* versene and the versene afterwards removed by sedimentation of the granules in the centrifuge and washing twice with 100 volumes of versene-free phosphate-chloride, the preparation ('washed versene' preparation of the accompanying table) was still relatively stable. Thus, such a preparation from rat heart was only 18–27 per cent inactivated by incubation for 15 min. at 25° C. As is shown in the table, the addition of calcium chloride increased the rate of inactivation. It also increased the rate of inactivation of a normal preparation in the absence of versene. It seems likely that versene stabilizes the preparations by virtue of its ability to remove calcium associated with the sarcosomes. The mechanism of the inactivation by calcium is not known.

Full details will be published elsewhere.

We wish to thank Prof. D. Keilin for his interest and advice. This work was carried out during the tenure of a grant from the Agricultural Research Council to one of us (E. C. S.), and of a Nuffield Dominion Fellowship to one of us (K. W. C.) during leave from the Department of Histology and Embryology, University of Sydney.

Note added in proof. The component of the reaction mixture chiefly responsible for the limited protection of the α-ketoglutaric oxidase system in the absence of versene is adenosine diphosphate. This is in agreement with recent work of Kielley and Kielley[9]. Magnesium, fluoride and phosphate together, but not singly or in pairs, also give considerable protection.

Glucose-6-Phosphate Dehydrogenase Activity of Rat Liver

A METHOD of assay of glucose-6-phosphate dehydrogenase in liver has been devised employing spectrophotometric measurement of the rate of reduction of triphosphopyridine nucleotide in suitably prepared liver homogenate supernatants. This is preferable to the determination of dehydrogenase activity in extracts of acetone-dried tissues[1], or to the use of unphysiological carriers such as brilliant cresyl blue, 2-6-dichlorophenolindophenol or phenazine methosulphate[2].

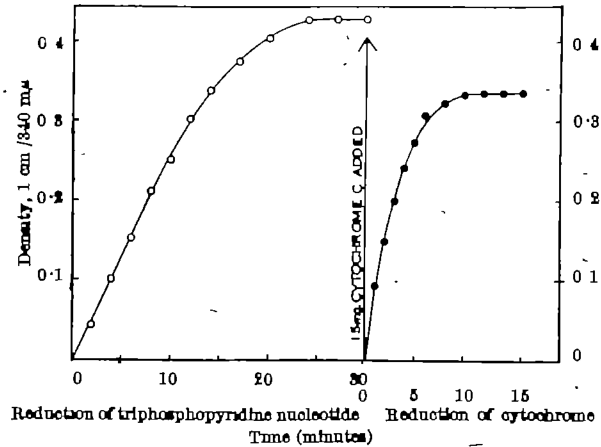

Fig 1. The reduction of triphosphopyridine nucleotide by glucose-6-phosphate dehydrogenase coupled with the enzymic reduction of cytochrome *c*.

The initial reaction mixture (total volume 2·5 ml.) included 0 1 ml. rat liver supernatant and 0 5 ml. veronal-acetate buffer *p*H 7 4, ± 0 2 mgm. 70 per cent triphosphopyridine nucleotide. The reaction was started by the addition of 0·1 ml. of 0·05 *M* glucose-6-phosphate to both cells. When the reduction was complete, excess (1 5 mgm.) cytochrome *c* was added to both cells Temperature 20° C.

Rat livers, chilled immediately after removal, were disintegrated in a Potter glass homogenizer in 4 volumes of ice-cold isotonic potassium chloride containing potassium bicarbonate to maintain the *p*H at 7·0, centrifuged for 60 min. at 4,000 *g* in an International refrigerated centrifuge and the supernatant dialysed overnight in the same cold extracting medium. This dialysed supernatant, which was free from triphosphopyridine nucleotidase and glucose-6-phosphatase, contained glucose-6-phosphate and 6-phosphogluconate-dehydrogenases and sufficient triphosphopyridine nucleotide–cytochrome *c* reductase[3] to be able to couple the reduction of triphosphopyridine nucleotide with that of cytochrome *c*. Results of a typical experiment with glucose-6-phosphate as substrate are given in Fig. 1. When the reduction of triphosphopyridine nucleotide was complete, excess cytochrome *c* was added and its reduction followed spectrophotometrically at 550 mμ. The rapid reduction of cytochrome *c* indicates that there are sufficient microsomes in suspension in the liver supernatant to provide triphosphopyridine nucleotide–cytochrome *c* reductase[4]. The reduction of triphosphopyridine nucleotide by the glucose-6-phosphate dehydrogenase system can also be coupled with the reduction of glutathione, as is indicated in Fig. 2 by the decrease in absorption at 340 mμ on addition of glutathione. This reaction is catalysed by glutathione reductase, which is associated with the combined soluble and microsome fractions of liver homogenates[5].

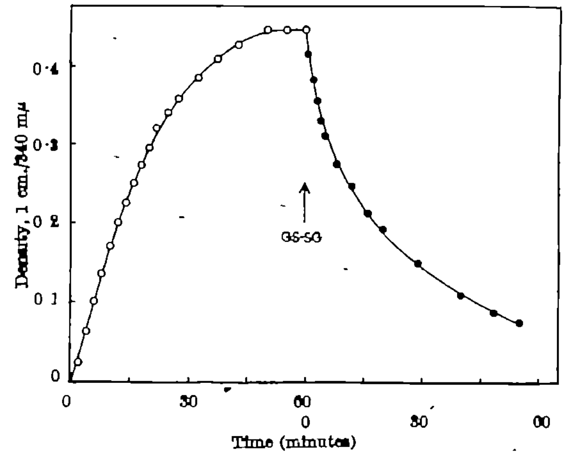

Fig. 2. The oxidation of reduced triphosphopyridine nucleotide by coupling glutathione reductase with glucose-6-phosphate dehydrogenase

The initial reaction mixture (total volume 2 5 ml) included 0 1 ml. rat liver supernatant and 0 5 ml. veronal-acetate buffer *p*H 7 4, ± 0 2 mgm. 70 per cent triphosphopyridine nucleotide. The reaction was started by the addition of a limiting concentration of glucose-6-phosphate (0 1 ml. of 0 005 *M*). When the reaction was complete, 0·2 ml. of 0 025 *M* glutathione was added to both cells. Temperature 20° C.

The reduction of triphosphopyridine nucleotide at 20° by the glucose-6-phosphate dehydrogenase system in these liver supernatants is linear for approximately 15 min. and proportional to enzyme concentration over a sufficiently wide range to make this method applicable to the quantitative estimation of glucose-6-phosphate dehydrogenase in liver.

The $Q^{20^\circ}_{O_2}$ per mgm. nitrogen for the glucose-6-phosphate dehydrogenase activity of seven pooled rat livers was 23·3, and the mean value and standard error on four individual rat livers was 21·15 ± 0·82. The mean (calculated) $Q^{37^\circ}_{O_2}$ for the latter group is 72 and was increased to 106 on spinning for a further 15 min. at 20,000 *g*.

These values indicate that the level of glucose-6-phosphate dehydrogenase in liver is sufficient for this system to be of physiological significance, and indeed for there to be active competition between the glycolytic and direct oxidative pathways for glucose-6-phosphate, their common substrate. It is also of interest that the enzymes of both the glycolytic[6] and direct oxidative pathways appear to be present exclusively in the soluble fraction of liver homogenates.

This work will be reported in detail elsewhere.

Polynucleotides from Deoxyribonucleic Acids

Dinucleotides are found among the products of deoxyribonuclease digestion of deoxyribonucleic acids. By fractionation of the digest on ion-exchange resins, Sinsheimer and Koerner[1] isolated a dinucleotide containing deoxyadenylic and deoxycytidylic acids and one containing deoxycytidylic acid only. Smith and Markham[2] treated the deoxyribonuclease digest with phosphomonoesterase, thus removing the terminal phosphoryl groups of the polynucleotides, and fractionated the resulting products by paper chromatography in 70 per cent *iso*propanol–water (v/v) in an ammonia atmosphere (solvent 1) into seven bands (numbered 1–7 in order of increasing R_F values). From these, by paper electrophoresis in ammonium formate buffer *p*H 3·5, they isolated six dinucleoside

PROPERTIES OF SOME DINUCLEOSIDE MONOPHOSPHATE DIESTERS AND RELATED SUBSTANCES FROM DEOXYRIBONUCLEIC ACID

G—p—C *G—p—MC* }	—	0·94	0·22	0·78	—	„ 4	3·0	„
A—p—C—p—T	0·97	—	1·03	—	1·00	„ 4	6·2	Herring sperm
A—p—C—p—T *A—p—MC—p—T* }	1·05	—	0·92	0·10	0·93	„ 4	6·2	Wheat embryo

monophosphate diesters, *A–p–C*, *A–p–T*, *G–p–T*, *C–p–T*, *C–p–C* and *T–p–T* (where *A* = deoxyadenosine, *G* = deoxyguanosine, *C* = deoxycytidine, *T* = thymidine and *p* indicates a phosphoric acid residue giving two nucleosides). These originated from the corresponding dinucleotides in the deoxyribonuclease digest.

We have now isolated these and several other substances from similar digests of wheat embryo deoxyribonucleic acid. This acid was chosen because of its singularly high content of 5-methyl cytosine[3] and was prepared via the deoxyribonucleoproteins by the method of Mirsky and Pollister[4]. The digestion of the deoxyribonucleic acid with deoxyribonuclease and phosphomonoesterase and the isolation of substances from the digest by paper chromatography and electrophoresis have been described fully elsewhere[2]. Identification of the substances rests on (1) quantitative analysis for purines, pyrimidines[3] and phosphorus[5], which gives the molecular size directly, as after the removal of the terminal phosphoryl groups the compounds contain (n) nucleoside residues and ($n - 1$) phosphorus atoms; (2) rate of migration on paper electrophoresis at pH 3·5 [6]. The hitherto undescribed dinucleoside monophosphate diesters found are *A–p–A*, *A–p–G*, *G–p–C* and *G–p–MC* (*MC* = deoxy 5-methyl cytidine). *G–p–C* and *G–p–MC* could not be separated from each other by paper chromatography in neutral, acid or alkaline *iso*propanol–water mixtures and, of course, migrate together on electrophoresis. They occurred together in band 4 of that chromatogram in solvent 1, which on paper electrophoresis in 0·05 *M* ammonium formate buffer pH 3·5 gave several bands of substances including one with a movement of 4·2 cm. (2 hr. at 20 V./cm.). This on analysis contained 0·94 mole guanine/0·22 mole cytosine/0·78 mole 5-methyl cytosine/1 mole phosphorus. The molar ratio of total bases to phosphorus is 1·94/1 (theoretical ratio for a mixture of dinucleoside monophosphate diesters, 2/1), and the molar ratio of guanine to (cytosine + 5-methyl cytosine) is 0·94/1 (theoretical ratio for a mixture of *G–p–C* and *G–p–MC*, 1/1). Some properties of these substances are given in the accompanying table.

In similar digests from herring sperm deoxyribonucleic acid we have also found a substance containing equimolar proportions of adenine, cytosine and thymine which we consider to be *A–p–C–p–T*, *C–p–A–p–T*, *A–p–T–p–C* or a mixture of these isomers. In digests of wheat embryo deoxyribonucleic acid this substance occurs together with small quantities of *A–p–MC–p–T*, from which it has not been separated. It is a nucleoside ester of a dinucleotide derived from a trinucleotide.

Similar methods have been used for the isolation of several dinucleotides and one trinucleotide from deoxyribonuclease digests (*without* phosphomonoesterase treatment). On paper chromatography in solvent 1, the components of the digest are fractionated into three bands. From these by paper electrophoresis we have isolated the dinucleotides *AC*, *AT*, *CT*, *GT*, *CC* and *TT*, and a trinucleotide containing *A*, *C* and *T*. Treatment of these with phosphomonoesterase converts them to the corresponding substances of the type described above.

With purified diesterase from Russell viper venom[7], the dinucleotide *AC* gives a mixture of deoxyadenylic and deoxycytidylic acids, both of which are dephosphorylated by a specific 5′ nucleotidase, demonstrating that the terminal phosphoryl group of the dinucleotide is attached to the 5′ position on a deoxyriboside residue. If *A–p–C* (derived from *AC* by phosphomonoesterase action) is treated with the viper venom diesterase, it is slowly hydrolysed, yielding deoxycytidine and deoxyadenylic acid. The latter is entirely converted to deoxyadenosine by the specific 5′ nucleotidase from Russell viper venom and is therefore deoxyadenosine-5′-phosphate. The terminal phosphoryl group of *AC* is thus linked to the deoxycytidine residue, which in turn is joined by a phosphate ester link to the 5′ position on the deoxyadenosine residue. As there is no evidence for internucleotide linkages in deoxyribonucleic acid other than phosphate-sugar ester links, it follows that *AC* is deoxycytidine, 3′(deoxyadenosine-5′-phosphate) ester, 5′ phosphate, and the diesterase splits preferentially the 3′ phosphate ester link.

While our experiments have not yet led to any simple formulation of the action of deoxyribonuclease, they do suggest certain features in the arrangement of nucleotides in the nucleic acid chain, notably with respect to deoxycytidylic and 5-methyl deoxycytidylic acids. In complete deoxyribonuclease digests, the ratio *GMC*/*GC* is much higher than that found for any other pair of dinucleotides differing only in the replacement of cytosine by 5-methyl cytosine. We are inclined not to attribute this to a specificity of deoxyribonuclease, but rather to the position of the 5-methyl deoxycytidylic acid residues in the nucleic acid chain.

We wish to thank the Wellcome Research Laboratories for a generous gift of Russell viper venom.

Biochemical Differences between Red and White Muscle

MYOGLOBIN, the principal pigment responsible for the red colour of muscle, was estimated by a method previously described by me[1]. The activities of components of the cytochrome system were determined in enzyme preparations[2] made from the muscles. Cytochrome oxidase was measured by determining the rates of oxidation of neutralized ascorbic acid in the presence of known amounts of added cytochrome *c* and extrapolating to infinite cytochrome *c* concentration[3]; succinic oxidase by the rate of oxidation of sodium succinate in the presence of excess cytochrome *c*[4]; and succinic dehydrogenase by the rate of reduction of methylene blue in the presence of excess sodium succinate, using the Thunberg technique[5]. Energy-rich phosphate ($\sim$ P), representing the sum of the labile phosphorus of adenosine triphosphate and of creatine phosphate, was determined as inorganic phosphate by Allen's method[6], after controlled hydrolysis of muscle extracts.

Both in Table 1, which represents data secured by analysis of muscle samples from the adults of various species, and in Table 2, in which are recorded figures for heart muscle from horses of different ages, it is evident that, in general, high myoglobin content in muscle is associated with high enzymic activity, particularly of cytochrome oxidase, in the corresponding enzyme preparations. This suggests that the function of myoglobin, with its power of reversible combination with oxygen and its low loading tension, is to assist in ensuring a constant supply of this element to the muscle oxidase system. The relatively low myoglobin content of horse heart and of pigeon breast muscle, despite high enzymic activity, may perhaps be explained by their possession of an excellent supply of oxygen from the blood, which is continually replenished by their characteristically repetitive contractions, thus partly dispensing with the need for an oxygen store. In contrast, the slow wing movements of the Manx shearwater, as compared with the more rapid ones of the pigeon, are reflected in a higher concentration of myoglobin in its pectoral muscle.

The other striking exception in the table to the general correspondence between myoglobin and the activity of the cytochrome system occurs in the psoas muscle of the blue whale. Its enzymic activity, which is very low in relation to the myoglobin content, helps to explain the diving capabilities of this mammal, for a low rate of oxygen utilization increases the length of time during which its relatively meagre store of myoglobin-bound oxygen could be effective. (When calculation is made to the same original weight of muscle, it is found that the whale psoas has an oxygen store at least twelve times greater, in relation to cytochrome oxidase activity, than that of the horse psoas.)

Table 1. RELATION BETWEEN ENZYMIC ACTIVITY IN MUSCLE PREPARATIONS AND MYOGLOBIN CONTENT IN CORRESPONDING WHOLE MUSCLE. EFFECT OF SPECIES AND TYPE OF MUSCLE

Muscle	Species	Myoglobin (% wet wt.)	Enzymic activity Q_{O_2} (µl. O_2/mgm. dry fat-free wt./hr.)

Table 2. EFFECT OF AGE IN HORSE HEART MUSCLE

Age	Myoglobin (% wet wt.)	Enzymic activity Q_{O_2} (µl. O_2/mgm. dry fat-free wt./hr.)		
		Succinic dehydrogenase	Succinic oxidase	Cytochrome oxidase
5 months before birth	0·02	negligible	20	200
6 weeks before birth	0·10	60	160	1,500
18 months after birth	0·27	240	580	2,700
2–12 years after birth (Mean of 6 animals)	0·33	210	610	2,800

It may also be noted from Table 1 that the activities of succinic dehydrogenase and of succinic oxidase in heart muscle apparently represent a greater proportion of the cytochrome oxidase activity than is the case in skeletal muscle. Similarly, in horse heart muscle (Table 2), with increasing age, succinic dehydrogenase and oxidase show a proportionately greater increase than does cytochrome oxidase over the same period. Data (not reported here) for the psoas, longissimus dorsi and diaphragm muscles of the horse also show this effect.

Apart from the above correlation between redness (myoglobin) and the activity of the cytochrome system, other differences have been found between heart, red, and white musculature. In skeletal muscle, the following bear an inverse relation to myoglobin content: (1) the initial resting level of energy-rich phosphate; (2) the ratio of rate of fall of *p*H under aerobic conditions to that under anaerobic conditions, and the ratio of rate of aerobic to anaerobic breakdown of energy-rich phosphate in post-mortem catabolism; (3) the rate of *p*H fall under anaerobic conditions; and (4) the 'maximum'[7] adenosine triphosphatase activity ('resting'[7] adenosine triphosphatase activity is about the same, irrespective of myoglobin content.) In other words, the more myoglobin in skeletal muscle, the greater appears to be its capacity for respiratory metabolism and the less its power for carrying out glycolytic processes; and conversely. Heart muscle appears to be unique in showing a virtual absence of glycolytic mechanisms—there is no detectable fall of *p*H under anaerobic conditions (in fact, a slight rise is often evident) and negligible anaerobic breakdown of energy-rich phosphates in post-mortem catabolism; the resting level of energy-rich phosphate is, moreover, very low. Adenosine triphosphatase activity is also very small and appears to be the same in 'resting' and 'maximum' conditions of activity. Heart muscle thus shows a profound dependence on oxygen for its functioning, with little or no capacity for incurring an 'oxygen debt'.

It is hoped to publish a full account of this work elsewhere.

Thanks are due to Dr. L. Harrison Matthews and Dr. Osman Hill, of the Zoological Society, London; to Mr. R. W. Pomeroy, of the School of Agriculture, Cambridge; and to Dr. J. G. Sharp, Mr. J. R. Bendall and Mr. J. K. Walley, of the Low Temperature Research Station, Cambridge, for making avail-

able various muscle samples. The encouragement of Prof. D. Keilin throughout these investigations is gratefully acknowledged.

The work described in this communication was carried out as part of the joint programme of the Food Investigation Organization, Department of Scientific and Industrial Research, and of the Scientific Adviser's Division, Ministry of Food.

Paper Electrophoresis of Serum Proteins

THE separation of the albumin, α_1-, α_2-, β- and γ-globulin fractions of serum protein can be accomplished by electrophoresis on filter paper[1-3]. The protein fractions are delineated as bands by drying the paper, and then staining with bromphenol blue. Cremer and Tiselius[2] estimated the fractions by elution of 5-mm. strips of the filter paper, the concentration of the dye from each strip being determined colorimetrically. A curve is thus obtained, similar to that from the classical Tiselius electrophoresis.

The separation by paper electrophoresis is elegant, and the apparatus simple, but the elution of dye from thirty to forty pieces of filter paper is both tedious and time-consuming, besides having theoretical objections. To simplify the procedure, and make it more adaptable for routine clinical laboratory analysis, we cut out, after staining, whole bands representing protein fractions and estimate the protein by Kjeldahl analysis of the filter paper. If an accurately measured amount of serum protein is used initially, the fractions are thus directly estimated in terms of protein nitrogen. This method gives duplicate results which appear to be as accurate as those obtained by the much longer procedure of elution. A comparison of the results of the analysis of a serum (converted into percentages of total protein) both by this method and that of the classical Tiselius separation is given herewith.

	Albumin	Globulins			
		α_1-	α_2-	β-	γ-
Paper electrophoresis	62 8	3 3	7·2	14·4	12 8
Tiselius electrophoresis (Veronal buffer, pH 8 6)	62·8	3·7	7·1	14 0	12·2

Full details of the method and the results obtained will be published elsewhere.

Inhibition of Lysine Decarboxylase from *E. coli* by Homologous Rabbit Antibody

IN studies on the production of antibodies to bacterial amino-acid decarboxylases, we have used lysine decarboxylase from a coliform organism as an antigen. This material was partially purified by a modification of the method of Gale and Epps[1] in order to reduce its toxicity for animals. The antigen, containing approximately 1·5 mgm. protein/ml., was injected intravenously into rabbits over a period of a month, at the rate of three injections a week. The dosage was gradually increased from 0·2 ml. to 1 ml. The rabbits were bled ten days after the final injection.

The antiserum was tested for inhibition of the lysine decarboxylase by the manometric method of Miller *et al.*[2]. Double side-arm Warburg flasks were employed, the antiserum being tipped in after the reaction had proceeded for twenty to thirty minutes. With the homologous enzyme, inhibition of decarboxylase activity was about 90 per cent complete. No inhibition of the corresponding glutamic acid decarboxylase preparations was noted, however, when antiserum to lysine decarboxylase was added under the same conditions.

When the antiserum and homologous enzyme were mixed and allowed to stand overnight in the refrigerator, a precipitate formed. The residual activity noted above was found only in the precipitate, showing that the enzyme is both precipitated and largely inhibited by the homologous antiserum. This positive finding is in contrast to the results recently reported by Happold and Ryden[3] for tyrosine decarboxylase from *Str. faecalis*.

A more detailed report of these experiments will be made in a doctoral dissertation to be submitted to Yale University by one of us (A. F. H.).

Reported Gamma Glutamyl Activation of Peptide-Bond Synthesis

IN a recent paper in *Nature*, Hanes *et al.*[1] postulated a γ-glutamyl transfer mechanism in peptide bond synthesis. It is suggested that the amino-acid forms its first peptide bond with the γ-carboxyl of glutamic acid by displacing the cysteinyl glycine from glutathione. The amino-acid, now peptide bound, could be further transferred to other peptides. The concept is strengthened in view of the universal and yet unexplained presence of glutathione in all living tissues, the great significance of 'transferring' reactions in biochemistry, and the need for some hypothesis to shed light on the mechanism of protein synthesis. Experiments to test this hypothesis are described in this communication.

Labelled γ-glutamyl glycine was synthesized using a micro adaptation of the method of LeQuesne and Young[2]. 40 mgm. of doubly labelled glycine (2·5 μC./mgm.) yielded 25 mgm. of peptide, the purity of which was verified by elementary analysis (theoretical C, 41·2 ; H, 5·9 ; N, 13·7 per cent ; found : radioactive C, 41·38 ; H, 6·01 per cent ; cold C, 41·31 ; H, 5·91 ; N, 13·58 per cent). The uptake of free radioglycine was compared to that of glycine in the presence of glutamic acid, glutamine, glutathione, and cold γ-glutamyl glycine. The systems studied were cytoplasmic particulate matter from rat liver suspended in cell supernatant (*PS* system)[3], whole cells of mouse spleen[4], spleen homogenate, and the Gardner lymphosarcoma of *C3H* mice[4]. The uptake of radiovaline (2-^{14}C-labelled 3·2 µC./mgm.) in the presence of glutamic acid, glutamine and glutathione in the *PS* system[3] and that of radiophenylalanine (2·38 µC./mgm., 2-^{14}C-labelled) in the presence of glutamic acid, glutamine, glutathione, and cold γ-glutamyl glycine in rat kidney homogenate were also studied.

In no case was there any appreciable activation of amino-acid incorporation by γ-glutamyl compounds. The uptake of glycine from the peptide was always appreciably less efficient than that of free glycine. The *PS* system used the peptide glycine three and a half times more efficiently than the spleen whole cell or homogenate.

'Dowex 50' chromatography of the free and peptide glycine showed that, in the liver particulate system, the peptide is 88 per cent hydrolysed in 20 min. and completely hydrolysed in 60 min. In spleen whole cells, the peptide is comparatively stable, 2 per cent being hydrolysed in 20 min. and 5 per cent in 60 min. This demonstrates a dependence of glycine incorporation on hydrolysis of the peptide in these systems.

In incubations with radioglycine at 20 min. and at 60 min., and with radioglycine plus cold γ-glutamyl glycine at 20 min., no radioactive γ-glutamyl glycine was present in the supernatant fluids. The liver particulate and spleen whole cell systems were used.

It is interesting to note that their reported stability to intercellular peptidases[1] was considered as evidence in favour of γ-glutamyl intermediates. The exceedingly rapid hydrolysis of the peptide in liver seems to eliminate this possibility.

These results cannot be interpreted in favour of γ-glutamyl activation as an important mechanism in amino-acid incorporation. Fuller details will appear in a later publication.

Purification of a Lipid Material ('Cord Factor') obtained from Young Cultures of Tubercle Bacilli

WHEN young cultures of wet tubercle bacilli are mildly extracted with petroleum ether, a small quantity of a lipid material ('cord factor') is obtained[1]. The most characteristic biological property of this material is a delayed type of toxicity. Mice injected at three- to four-day intervals with 0·1 mgm. of the crude extract die after ten to fourteen days, severely emaciated and with hæmorrhages of the lungs. The crude material gives negative reactions for phosphorus[2] (sensitivity < 0·1 per cent phosphorus) and for nitrogen[3] (sensitivity < 0·4 per cent nitrogen).

The characteristic toxicity described was used as a biological test for the identification of the material during its further purification. The crude extract was repeatedly heated in acetone to the boiling point and the clear supernatant decanted immediately. Thus, an acetone-soluble fraction (*A*) is obtained, representing about 99 per cent of the total material. The residue which, under these conditions, remains undissolved (fraction *B*, about 1 per cent) shows the characteristic toxicity, whereas *A* is inactive. Fraction *A* consists chiefly of neutral constituents (mainly phthiocerol), mycolic and other acids, and carbohydrates. A detailed report on these constituents will be published. Fraction *B* is soluble in cold petroleum ether, benzene, chloroform and ether, and insoluble in methanol, ethanol and water. After heating it for about thirty minutes in large volumes of boiling acetone, it can be brought into solution, but it is precipitated again from the cold solvent. It is likewise negative for phosphorus (< 0·05 per cent phosphorus) and nitrogen (< 0·09 per cent nitrogen).

Upon alkaline hydrolysis with methanolic potassium hydroxide in the presence of benzene (80° C., 8 hr.) fraction *B* yields three different fractions : (1) neutral compounds and ether-soluble salts of acids ; (2) ether-insoluble salts of acids ; (3) a water-soluble part, containing the carbohydrates liberated by saponification.

After hydrolysis, fraction (2), which contains the acids, appears as an oily residue. This fraction shows the biological activity of the original material. It is obtained only in minute amounts.

Samples of lipopolysaccharides from tubercle bacilli[4] were kindly supplied to us by Drs. E. Lederer and J. Asselineau. Their material, which is insoluble in hot acetone, did not show the characteristic toxicity of our fraction *B*.

Toxic Principle of *Lathyrus sativus*

THE toxic substance of *L. sativus* responsible for lathyrism has been identified as selenium. *L. sativus* is much richer in selenium content than other pulses which are harmless (see table). Selenium has been estimated after wet incineration of the dried substance and reduction with ascorbic acid, which is a stronger reducing agent than hydroxylamine used by Klein[1]. Owing to the higher degree of utilization of *L. sativus* (Jiménez Díaz and Romeo[2] observed 86 per cent utilization) the high selenium content is easily transported to the tissues.

Pulse	Selenium content (mgm./100 gm. dry)
P. radiatus	2·5
P. sativum	1·2
C. arietinum	5·0
L. esculenta	2·3
L. sativus	22·9

Selenium has been given intraperitoneally to the monkey beginning with a dose of 500 µgm. and ending with 820 µgm. daily. In a period of eighty-four days, there were thirty-six blank days and forty-eight injections of a total of 31·23 mgm. selenium. After forty-one injections, extensor plantar (upturning of the hallux on stimulation) was first observed. The first sign of abolition of abdominal reflex was observed after forty-three injections. Flaccidity, the sign of ablation of area 4 [3], was also present. The upturned hallux after selenium administration in the monkey is very significant. The sign is produced in man and anthropoids when the pyramidal tract is interrupted; in the monkey, only when the entire cerebral hemisphere is removed[4]. Evidently selenium has not only caused degeneration of the pyramidal tract but has also produced more widespread lesions in the cerebral cortex. After the total dose of 31·23 mgm. of selenium, alkaline serum phosphatase was found to be increased to 90 King and Armstrong units[5], as compared to 14 units in the normal animal. Rudra and Bhattacharya[6] had previously observed that alkaline serum phosphatase is raised in lathyrism.

One of the mechanisms of action of selenium is by interference with methionine metabolism. In lathyrism patients who are still consuming the vetch pea, the methionine excretion falls to a fifth of the normal, the excretion rising to normal as soon as other pulses are substituted for the vetch pea[7]. Very early anorexia and gastrointestinal disorders are probably due to a disturbance in aneurin metabolism. Marked dermatitis may be due to some disorder in biotin utilization, since biotin is interrelated with fatty acid metabolism. We interpret these observations as due to selenium competing with sulphur. There is some indirect evidence that in lathyrism (due to selenium intoxication) the transmethylation process may be interfered with. Gillis and Norris[8] report that vitamin B_{12} helps the trans-methylation process. Rudra *et al.*[9] observed that motor neurone lesions in lathyrism patients are healed (extensor plantar becomes flexor; abdominal reflex) when methionine is given with vitamin B_{12}, while methionine given alone has no effect.

We are of opinion that selenium may interfere with enzyme systems requiring the sulphydryl or sulphamethyl groups for activity. The investigation is being continued.

We are indebted to the British Drug Houses, Ltd., for the gift of sodium selenite.

Toxicity of Dextran in Rats

The anaphylactoid reaction caused by dextran in rats has recently been studied by several investigators[1-3]. We have found that after intradermal injections of dextran dissolved in physiological saline (in rats), Menkin's intravenous dye test[4] shows a seepage of dye into the wheals when the concentration of commercial dextran (Macrodex, Pharmacia Inc.) is at least 10 µgm./ml. Moreover, it has been found that dextran preparations with highly branched molecular chains are more toxic than those with relatively unbranched chains. Dextran fractions of an average molecular weight of 10,000 cause a positive dye test only in concentrations of about 10 mgm./ml. Sulphuric acid esters of dextran[5] do not cause increased capillary permeability. We have confirmed the previously reported increase in hæmatocrit values after intravenous injection of dextran[3], and found that it is more or less completely prevented by antihistaminics, local anæsthetics and pretreatment with cortisone in high doses. The most potent inhibitor, however, is alloxan intravenously in a subdiabetogenic dose. 2,3-Dimercaptopropanol injected 30 min. before dextran has an inhibitory effect only in some experimental series. The factors causing these variations in the 'antiphlogistic' effect of *BAL* are under study.

Viability of *Conispiculum guindiensis* in *Calotes versicolor* Preserved in Formalin

Several specimens of *Calotes versicolor* (a garden lizard) were collected from gardens in Guindy near Madras, during March 1949. Blood, exuding from their cut tails, was examined for filarial infection. Six calotes found positive with microfilariæ of *C. guindiensis* were killed by the use of chloroform. Before preservation in formol-saline (one part of commercial formalin to four parts of normal saline) a 2-in. slit was made in the abdominal wall to open it. The specimens were brought to Delhi for demonstrating the adult worms *in situ*. In one specimen, which was dissected fourteen days later, although some degree of putrefaction had taken place, viable filarial worms were seen. Some of the adult female worms contained ova which stretched out to typical microfilarial forms. Similar findings were observed in the remaining calotes dissected at weekly intervals. The last two calotes were dissected in the sixth week of preservation. Temperature during that period ranged from 97·0° F. maximum to 51·0° F. minimum.

Similar results were observed in another batch of four calotes caught from the same area during March 1951. In yet another lot of four calotes, commercial formalin was used as a preservative, but all worms were found dead within a week of preservation. This indicates that formol-saline, though it inhibited bacterial growth, did not kill the worms or the ova in them.

Effect of Nitrite on the Nuclear Structure in the Silkworm

It has already been observed[1] that nitrites caused the production of virus in the body of the silkworm. It is thus to be expected that changes of cellular structure in the worm may be provoked by nitrites. For the purpose of confirming this assumption, I have now conducted several experiments and prepared a large number of specimens.

In one experiment, I bred a virus-free strain in spring. On the first day of the fourth instar, larvæ were divided into two groups. The first group was fed with potassium nitrite once each day. The concentration of nitrite solution given was 2·8 per cent for the first three days, but it was later increased to 4·3 per cent. The second group was reared in an ordinary way. At regular intervals, the adipose tissues from worms of both groups were spread on glass slides, fixed in acetic acid-alcohol and stained with Delafield's hæmatoxylin.

It was found that cells of silkworms receiving nitrite showed abnormal morphological changes. The accompanying photograph is of a preparation made two days after the beginning of chemical feeding. In general, three kinds of abnormalities were observed: swelling of nuclei, aggregation of chromatins and amitosis. In caterpillars which had not received nitrite, the size of nucleus was much smaller, and I could not observe these anomalous phenomena. On the seventh day of the fourth instar, the nuclei in fatty tissues of larvæ of the group receiving nitrite were filled with the polyhedral virus. All the individuals of the second group, however, remained perfectly healthy.

I suggest that, as a result of nitrite feeding, a kind of denaturation may take place on genes of the cells of the silkworm. The genes denatured are endowed with an abnormal ability of reproduction and multiply independently. The multiplication of such genes is accompanied by a special rearrangement of cellular constituents. After a certain period, a definite number of independent genes combine together with re-arranged components, and masses of extraordinary size—virus particles—are thus formed in nuclei. This seems a possible mechanism of chemical virus production.

Some Effects of Ultra-violet Radiation on *Lemna minor*

In view of the fact that treatment with ultra-violet radiation has become a common technique in physiological and genetical work, the following observations we have made on the effect of ultra-violet radiation on *Lemna minor* may be of interest.

We used a 'Vitreosil' mercury vapour discharge lamp $T/M5/369$, which emits radiation mainly in the region of 2500 A. During irradiation the plants were floating on water in small beakers 20 cm. vertically underneath the lamp.

In the early experiments, the plants and the ultra-violet lamp were enclosed in a box during treatments. A strong smell of ozone developed in the box. Treatment for more than 10 sec. produced visible symptoms in the fronds, namely, the exudation of drops of liquid from the upper epidermis. Treatment for more than 30 sec. was lethal: the fronds lost their chlorophyll overnight and died in a few days.

Ultra-violet radiation was accompanied by the production of ozone. Accordingly we investigated the possibility that these symptoms were due to ozone in the atmosphere and not to the ultra-violet radiation *per se*. This possibility does not seem to have received attention in the literature on effects of ultra-violet radiation. Popp and Brown[1] do indeed mention experiments in which plants were exposed to "the ozone only" of the lamp; but they do not say whether there was any effect. To test the effect of ozone alone we left the ultra-violet lamp on for two minutes, with the box closed and empty. The lamp was then switched off, and the plants were put into the box without any ultra-violet radiation and were left in it for varying lengths of time. Under these conditions the same symptoms appeared after the same lengths of treatment as in the earlier experiments, although there was no ultra-violet radiation present.

In a third experiment *Lemna* plants were irradiated as in the first experiment, but two opposite walls of the box were removed and a strong current of air was blown over the surface of the plants to remove the ozone. Under these conditions the amount of irradiation which could be given in a single dose without producing visible symptoms was increased from 10 sec. to about 90 sec. The minimum lethal dose was increased from about 30 sec. to about 600 sec. The symptoms of damage by ultra-violet radiation are somewhat different from those due to ozone alone—for example, ultra-violet radiation without ozone does not cause rapid destruction of chlorophyll. During these final experiments we noticed that plants were affected by the ozone if they happened to be in the same room, even when they were a few yards away from the source of radiation.

We conclude from these observations that if ultra-violet lamps are used in experiments with biological material, care must be taken to distinguish the effects of the radiation *per se* from those of the ozone produced by it.

Identification of Tertiary Pollen Grains with those of New Guinea and New Caledonian Beeches

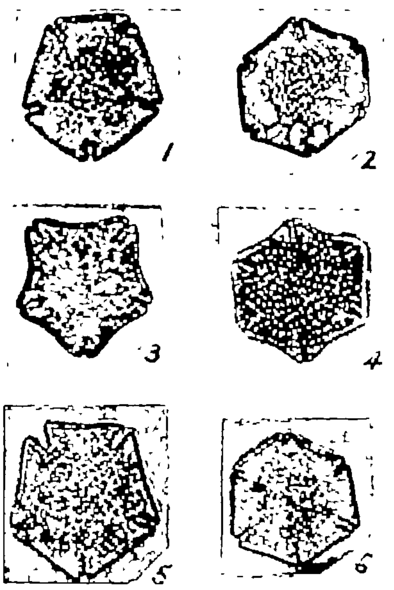
SEVERAL years ago, when certain pollen grains from Tertiary deposits in south-eastern Victoria were referred to the genus *Nothofagus*[1], it was recognized that some of them seemed to be intermediate in form between the two types of pollen grains that normally occur in this genus. At that time these divergent types were believed to be the pollen grains of extinct species of *Nothofagus*, and, as such, it seemed doubtful whether their exact affinity would ever be determined.

Examinations of the pollen grains of one of the New Guinea beeches, first discovered by Pulle in 1912 and independently recognized as *Nothofagus* by Brass and van Steenis in 1939, and of another beech discovered quite recently in New Caledonia by Dr. Baumann-Bodenheim, have shed light on the affinities of the fossil pollen. The pollen grains of both trees fall neither into the *menziesii* pollen group (*N. menziesii*, *N. cunninghami*, *N. moorei* and *N. obliqua*) nor the *fusca* group (*N. fusca*, *N. truncata*, *N. solandri*, *N. cliffortioides*, *N. gunnii* and, according to Cranwell[2], the bulk of the South American species) but are similar to the Tertiary pollen grains referred to by Cookson as *N.* sp. *e*.

This close agreement between the living and fossil pollen grains (Figs. 1–6) implying, as no doubt it does, a close affinity between the parents of each, indicates a long past-history and a far wider geographical distribution than at present. *N.* sp. *e*., which is probably the commonest of the Australian Tertiary pollen types, has been observed, sometimes in large numbers, in deposits that range from southern Queensland to Tasmania and westward into South Australia. Similar, if not identical, 'intermediate' pollen species have been distinguished in Cretaceous and Tertiary beds in New Zealand[3].

Several morphological and anatomical distinctions between the New Guinea beeches and other species of *Nothofagus* have already been observed by Langdon[4], who has remarked that "in certain respects they are sufficiently unlike the more typical members of that genus to justify their reference to a new section of the evergreen beeches". Their pollen morphology, so far as it is known at present, supports this statement.

Male flowers of the New Guinea species mentioned were collected by Mr. A. Schindler at Aiyura in the Eastern Highlands Division of New Guinea, and kindly forwarded to me by Mr. J. S. Womersley, Forest botanist, Department of Forests, New Guinea.



(1) and (2) Acetolysed pollen grains of *Nothofagus* from Aiyura, New Guinea. × 600
(3) and (4) Acetolysed pollen grains of *Nothofagus* from New Caledonia. × 600
(5) and (6) Acetolysed pollen grains of *N.* sp. *e*. from Oligocene clay, Yallourn, Victoria. × 600

Anthers of one of the New Caledonian species were generously supplied by Dr. M. G. Baumann-Bodenheim, of the Botanical Gardens, Zurich.

Secondary Piliferous Layer in the Lupin

THE communication by J. B. Goodey on a secondary piliferous layer in *Hippeastrum*[1] leads me to record a similar structure in *Lupinus*.

During the examination of seedlings of *Lupinus arboreus* grown in the laboratory, a yellow gelatinous layer was noticed to appear on the roots simultaneously with the emergence of root hairs. This layer was found to consist of the disorganized cells of the epidermis and the two outer layers of cortex. Root hairs had originated in the third layer of cortical cells and penetrated the outer layers of smaller cells either directly or after some distortion. No root hairs were seen arising from epidermal cells.

In culture, seedlings were not infected by nematodes; but plants growing in the wild on the drier parts of sand dunes were highly susceptible to attack. Seedlings in this habitat all had exceptionally heavy developments of root hairs.

FORTHCOMING EVENTS

Monday, July 21—Thursday, July 24

SOCIETY FOR APPLIED BACTERIOLOGY (at Cambridge).—Summer Meeting and Annual General Meeting.

Thursday, July 24

Symposium on "Aspects of Food Preservation".

Monday, July 21—Friday, July 25

BRITISH ECOLOGICAL SOCIETY (in the Department of Botany, University College, Southampton).—Summer Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH DEMONSTRATOR IN GEOGRAPHY—The Registrar, The University, Sheffield (July 25).

DIRECTOR OF THE RESEARCH ESTABLISHMENT which the Board is setting up at Isleworth, Middlesex (the Establishment will be concerned with all underground activities connected with the mining of coal, and the principal qualifications for the post are proved ability in research in some branch of engineering or physics allied to engineering, and in directing teams of research workers)—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/499 (July 26).

TEMPORARY ASSISTANT LECTURER IN MATHEMATICS—The Principal, Royal Holloway College, Englefield Green, Surrey (July 28).

ANALYST IN THE CHEMISTRY OF INSECTICIDES AND FUNGICIDES SECTION—The Secretary, Long Ashton Research Station, Long Ashton, Bristol (July 31).

LECTURER IN CHEMISTRY (with special qualifications in physical chemistry)—The Registrar, University College, Cathays Park, Cardiff (August 2).

TECHNICAL SECRETARY (with a university degree in science or agriculture, or equivalent qualifications, previous administration and secretarial experience would be an additional desirable qualification) in the Division of Biochemistry and General Nutrition, University of Adelaide, Adelaide, to assist the Chief of the Division in matters relating to the administration of the Division, including preparation of reports, handling of technical inquiries, and technical correspondence—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3668 (August 9).

LECTURER (Grade II) IN CIVIL ENGINEERING, and a LECTURER (Grade III) IN THE DEPARTMENT OF PHYSIOLOGY—The Registrar, The University, Birmingham 15 (August 11).

RESEARCH FELLOWSHIPS IN THE DEPARTMENT OF ELECTRON PHYSICS—The Registrar, The University, Birmingham 15 (August 12).

ASSISTANT PROFESSOR OF BIOCHEMISTRY—The Chairman, Department of Biochemistry, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia, Canada (August 15).

LECTURERS IN EXPERIMENTAL AND MATHEMATICAL PHYSICS—The Assistant Secretary of University Court, The University, Glasgow (August 15).

SENIOR LECTURER IN PHYSICS in the University of Natal, Pietermaritzburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (August 15).

SENIOR LECTURER IN CHARGE OF THE DEPARTMENT OF PHARMACOLOGY, and a LECTURER OR ASSISTANT LECTURER IN THE DEPARTMENT OF PHYSICS, at the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (August 30).

ASSISTANTSHIP IN PHYSIOLOGY—The Assistant Secretary of University Court, The University, Glasgow (September 1).

PRINCIPAL—The Clerk to the Governors, National Leathersellers College, 15 St. Helen's Place, London, E.C.3 (September 1).

SENIOR LECTURERS (2, qualified architects and Fellows or Associates of the R.I.B.A., with considerable practical and teaching experience) IN ARCHITECTURE, at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 1).

SENIOR LECTURER OR LECTURER IN PHYSIOLOGY at Makerere College, University College of East Africa—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 20).

READERSHIP IN MEDICAL PARASITOLOGY at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 23).

LECTURER IN PHYSICS (with special qualifications in theoretical physics)—The Secretary, Queen's University, Belfast (November 30).

ASSISTANT AGRICULTURAL ECONOMIST to undertake research and investigational work—The Registrar, Wye College, Wye, Ashford, Kent

ASSISTANT BIOCHEMIST (with a degree or equivalent qualification in chemistry) to undertake clinical biochemistry work—The Secretary, Welsh National School of Medicine, 34 Newport Road, Cardiff.

ASSISTANT (Grade B) to lecture in the DEPARTMENT OF PHARMACY AND BIOLOGY—The Registrar, College of Technology, Suffolk Street, Birmingham 1.

CHEMIST in the Division of Atomic Energy (Production), at Windscale Works, Sellafield, to be responsible for the supervision and operation of small-scale chemical plants processing radioactive materials—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting Ref. 362.

ELECTRICAL ENGINEER in the Division of Atomic Energy (Production), to be responsible for the efficient upkeep and maintenance of the electrical plant in the production group of a large factory at Capenhurst, Chester—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting Ref. 360.

EMPIRE RHEUMATISM COUNCIL FELLOWSHIPS (medical or scientific qualifications are needed) to prosecute research in the field of rheumatism—The General Secretary, Empire Rheumatism Council Tavistock House (N), Tavistock Square, London, W.C.1.

HEALTH PHYSICS AND SAFETY GROUP MANAGER (with a knowledge of radioactivity or electronics) in the Division of Atomic Energy (Production), to take charge of a group concerned with the investigation, measurement and control of radiation in a large nuclear chemical factory at Springfields, Salwick—The Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting Ref. 357.

HONOURS GRADUATE IN PHYSICS, or related field, to work in Aberdeen on problems of smoking and drying of fish, including investigation of the physical properties of smoke and of the diffusion of water in fish—The Secretary, Herring Industry Board, 1 Glenfinlas Street, Edinburgh 3.

LECTURER IN THE MECHANICAL ENGINEERING DEPARTMENT of the Municipal Technical College—The Chief Education Officer, Guildhall, Kingston-upon-Hull.

LECTURER IN PHYSIOLOGY (honours graduate in physiology of a British university) for the Hygiene and Public Health Department—The Clerk to the Governing Body, Battersea Polytechnic, Battersea, London, S.W.11.

MICROBIOLOGIST at the Colonial Microbiological Research Institute, Trinidad—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref 27069/324

PHYSICIST (with good honours degree) to be concerned initially with the processing of textile fibres, both from a practical and theoretical point of view; an interest in statistical methods is desirable, but not essential—The Secretary, British Jute Trade Research Association, Kinnoull Road, Kingsway West, Dundee.

POST IN THE PHYSICS DEPARTMENT (candidates should have a first or second-class honours degree in physics) to assist in research on the properties of dairy products—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 52/8.

RESEARCH ASSISTANTSHIPS (honours graduates with sound general training in either chemistry or physics) in the recently formed research group of the Department of Applied Science, Wolverhampton and Staffordshire Technical College—The Clerk to the Joint Education Committee, Education Offices, North Street, Wolverhampton.

SCIENTIFIC ASSISTANT (with a degree in a biological science related to the work of the Bureau, some ability in and interest in Bureau work, and some knowledge of various languages) for work in connexion with the abstracting, reviewing, and indexing of the literature dealing with veterinary science—The Director, Commonwealth Bureau of Animal Health, Veterinary Laboratory, Ministry of Agriculture and Fisheries, New Haw, Weybridge, Surrey.

SCIENTIFIC RESEARCH AND MAN-POWER PROBLEMS

QUITE apart from the fact that it elicited from the Lord President of the Council some indication of the Government's intentions in regard to the Science Centre and the expansion of higher technological education (cf. *Nature*, June 21, p. 1039), the debate in the House of Lords on June 11 and 12 on science and industry is of considerable interest as providing the commentary which the Advisory Council on Scientific Policy might otherwise have been expected to supply in publishing recently the report of its Committee on Scientific Man-power. The debate was initiated by Lord Samuel on a motion asking for a statement on the use made by industry and agriculture of the results of scientific research, and on the Government's policy for promoting the higher education of technologists. Lord Samuel himself commented at some length on the man-power report, stressing particularly the need for a broadly based system of technological education. Lord Woolton, before dealing with this latter question, reviewed briefly the whole Government organization for research, through which some £16,000,000 a year is spent directly on civil scientific research, apart from the £18,000,000 provided by the Treasury for the universities, a considerable part of which is spent in training scientific men. Much of what he said related to the Department of Scientific and Industrial Research, and this part of his speech, as well as further comments in the debate and replies from the Government side, throws some light on the Government's attitude to some disquieting features of that Department's last annual report.

Lord Woolton, after citing examples of substantial returns which had accrued from work under the Department of Scientific and Industrial Research, expressed general satisfaction with the extent of applied research being carried out in Great Britain, though not with the way in which its results are being applied in industry. In asking the Advisory Council on Scientific Policy to review the effectiveness of current arrangements for ensuring that the results of research make their full contribution to the development of the British economy, the Lord President no doubt had in mind some extension of the survey of the organization for research which was carried out by the Select Committee on Estimates in 1947. The Survey Panels which have already been set up to survey the resources and work of particular research associations in relation to the needs of their industries are evidence that the expenditure and efficiency of the Department of Scientific and Industrial Research are being closely examined from within.

A number of comments made during the debate supported this realistic policy, and Lord Falmouth, in particular, pressed for close examination of the vote for research and development under the Ministry of Supply, which now stands at £100,000,000 and has increased by £18,000,000 on last year; this is more than three times the total expenditure on the Department of Scientific and Industrial Research.

In this context the support given in the Lords debate to the plea of the Advisory Council for Scientific and Industrial Research for action to deal with some of the more urgent items in the Department's building programme is the more impressive. Lord Woolton explained that the construction of a modern tank for shipbuilding tests was delayed not on financial grounds but by design difficulties, and assured the House that the project would go ahead as soon as the design is available. Neither he nor Lord Cherwell replied, however, to Lord Crook and Lord Halsbury or other speakers, who strongly supported the Advisory Council's plea for greater flexibility in regard to the Department's expenditure, and particularly that the Department should be permitted to carry over unspent balances and allowed some increase of expenditure of the order of five per cent until its post-war plans are fulfilled.

On the whole, however, the trend of Lord Woolton's and Lord Cherwell's observations warrants some confidence that the support forthcoming for the Advisory Council for Scientific and Industrial Research in this debate will not be without effect. Nor did the Advisory Council's remarks on the man-power situation in the Department pass unnoticed. Many speakers seemed inclined, indeed, to probe that situation more deeply, and especially the observation in the man-power report of the Advisory Council on Scientific Policy that many of the best science graduates appear to be attracted to employment outside the Government scientific service. Lord Pakenham rather discounted the suggestion that inadequate salary-scales are responsible for the difficulty the Department of Scientific and Industrial Research and the Agricultural Research Council are experiencing in obtaining recruits of sufficiently high quality, and urged that it is rather a matter of prestige and of the removal of any barriers which prevent scientific men with administrative gifts from rising to the highest positions.

More may well depend on the conditions of service than Lord Cherwell seems disposed to concede. Conditions are liable to be more restrictive in Government service and, in the main, those conditions, as regards freedom of publication and the like, may not compare unfavourably with those in industry, as Lord Cherwell suggested. Nevertheless, his reference to freedom of movement between men of science in Government service, universities and industry was not too happily phrased and could convey the impression that such movement is regarded with disfavour generally, instead of being restricted or discouraged only in respect of those who have been working on the most secret subjects in Government service.

While Lord Cherwell's attitude here is right and reasonable, it could have been accompanied by some indication that, on the Government side, it is appreciated that any such limitation, however necessary, is a handicap to the advance of science and to industrial development. Misapprehensions are not removed by brusqueness, and, while more attention to general education, as freely emphasized in the debate, may remove a deficiency in the training of scientific men to which the Advisory Council on Scientific Policy directed attention in its fifth report, it will not of itself overcome the reluctance to enter Government service. More attention to the question of status and to like psychological factors appears to be desirable, both from the point of view of recruitment and of ensuring that the best use is made of the services of scientists and technologists and of the results of their work.

Lord Wise referred to the importance of exchange of staff between different institutes and between industry and the colleges of technology, from the point of view of improving standards of training in technology. Government establishments, and notably the research associations of Britain, have their part to play also, and it should be possible for the Lord President of the Council by his policy here to dispel any misgivings that Lord Cherwell's speech may have encouraged. The siting of the proposed new technological university and the choice of the few colleges of technology to be raised to university status should also have regard to the way in which proximity to a university and to centres of industry could foster both exchange of staff and co-operation.

Prof. R. S. Edwards, in a paper in the January issue of *Lloyds Bank Review*, lays much stress on the importance of closer collaboration between universities, research associations and government research establishments, as well as between the universities and industry. He, too, believes that we have still a long way to go before British industry is fully accustomed to the idea of employing university graduates, and that it will be some time before application enjoys the same prestige as pure research. Here, as in his emphasis on the importance of industry being well supplied with men and women capable of understanding the interplay of scientific, technological and market forces, and of framing and executing appropriate policies, he is in agreement with the findings of the man-power committee of the Advisory Council on Scientific Policy, and indeed some of his conclusions and suggestions are more specific.

On this question of co-operation, Prof. Edwards makes three important points. First, referring to the research associations, he stresses the substantial contributions to technological education which such associations could make. Where it is, in fact, being made, he considers it alone justifies support of an association. Financial partnerships between industries and the State on these lines are sound, he urges, provided that there is no pampering, that the negotiation of grants is hard-headed and business-like, that the Government makes sure it gets value for public money, and that it does not keep sickly associations alive too long. It would seem from Lord Woolton's speech that he is already alive to the implications of this view.

Prof. Edwards's second point concerns the universities as well as the research associations. While he considers our research institutions are well adapted to our present needs, he expects the demand for facilities for sponsored research to grow as more scientists and technologists are employed in British industry and technological competition becomes keener. He believes that the research associations should play a part in meeting this need, and that they could, as an extension to the existing advisory services, develop facilities for sponsored projects which do not clash with their co-operative programme without imperilling the co-operative nature of the associations. The universities also should participate in this field, and Prof. Edwards believes that they could do so, with appropriate safeguards and proceeding cautiously, without endangering either academic freedom or distorting their research programme.

One reason given by Prof. Edwards for advocating such a step, which admittedly is not at present favoured in academic circles, is that an increase in the volume of sponsored projects in the universities would raise the prestige of industrial research and application among young scientific workers and would be an additional source of university finance. In the light of the report of the Advisory Council on Scientific Policy, any measure that promises to break down the reluctance of promising students to enter on a scientific and an industrial career should be considered with an open mind, and Prof. Edwards's suggestion should be noted particularly with reference to research in technological institutions, on which stress was laid by Sir John Cockcroft in an article in the May issue of the *Universities Quarterly* as well as in the House of Lords debate. Prof. Edwards's third point is indeed that there should be closer collaboration between universities, research associations and government research establishments in regard to postgraduate studies. He visualizes, for example, research associations collaborating with the universities and the colleges of technology to provide some of the facilities for postgraduate work, on the meagreness of which Sir John Cockcroft pointedly commented.

Such a measure should supplement, rather than be a substitute for, the more generous provision of means for postgraduate research in the technological departments and the colleges of technology themselves. The possibilities in this direction should be carefully examined as part of the policy for the development of higher technological education. This in itself is an urgent reason for placing the responsibility for technological education in the same hands as are responsible for university education. It is to be hoped that at least the House of Lords debate will bring home to the Government the need for definite action in this respect, and for relieving the Minister of Education of this anachronism in her responsibilities.

It is of course, clear from the circumstances of the speeches in the House of Lords that few new points could be contributed to the discussion of the organization of civil research and the recruitment of scientific workers. Its realistic tone was, however, encouraging, and should help to ensure that a close watch is kept to see that the nation gets a full return from its investment in research, and that financial parsimony does not impair efficiency or hold up essential developments.

MORE OLD CAMBRIDGE MEN

Alumni Cantabrigienses

A Biographical List of all known Students, Graduates and Holders of Office at the University of Cambridge, from the Earliest Times to 1900. Compiled by Dr. J. A. Venn. Part 2: From 1752 to 1900, Vol. 4: Kahlenberg–Oyler. Pp. iv+615. (Cambridge: At the University Press, 1951.) 150*s*. net.

ON looking through this volume one is once more struck by the very high proportion of members of the University of Cambridge during the years 1752–1900 who took orders in the Church of England after leaving the University. This is to be explained in part by the fact that the University was for the greater part of the period closely linked with the Church; but that is not the only reason for the change that is to be found in the proportion of clerical graduates to-day. Careers for university graduates were more limited in range in this earlier period; the Church, schoolmastering, an academic career, the professions of medicine and law, the army, diplomacy, the Civil Service, the Indian Civil Service and the Colonial Service, such business careers as banking and publishing—these covered the chief openings for university graduates. Some men joined their fathers' businesses, but posts in industry and business generally were not offered as a rule to university men.

The biographies of individuals in the book are necessarily short; but a number of interesting facts emerge even from a casual study of the volume. Thus we learn that Prof. Herbert Marsh, F.R.S., Lady Margaret professor of divinity, 1807–39 (and simultaneously Bishop first of Llandaff and then of Peterborough), was the first to give his professorial lectures in English, instead of in Latin. Another divine who made a name for himself was the Rev. T. R. Malthus, F.R.S., known not unnaturally as "Old Pop". Of the Rev. Eward Kempe we are told that he left a ton of unpreached sermons behind him. Schoolmasters include the great flogging master, John Keate, of Eton. Naturally a large number followed an academic life—we will only mention here Prof. George Liveing, professor of chemistry for more than forty years, who died at the age of ninety-seven, James Clerk Maxwell, the first Cavendish professor, and Bartholomew Lloyd, who was incorporated D.D. in 1833 from Trinity College, Dublin. He was then Provost of Trinity, having previously been successively professor of mathematics, professor of natural philosophy, regius professor of Greek and lecturer in divinity. The Army provides Teignmouth Melvill, who earned the Victoria Cross at Isandlwanha in the Zulu War. In diplomacy we will mention two exceptional types: Thomas Manning, friend of Lamb, the first Englishman to enter Lhasa, a great Chinese scholar, and Henry Labouchere, who contracted £6,000 of debt in two years in Cambridge, joined a circus troupe, lived for six months in a Red Indian camp, then entered the diplomatic service, was dismissed for impertinence to Lord John Russell, became an M.P., and then a successful journalist with the *Daily News* and *Truth*.

About ninety Fellows of the Royal Society appear in this volume, of whom some half-dozen happily survive to-day; there is a very marked concentration among the names commencing with 'Mac' or 'Mc'. Among the honorary graduates who were also distinguished in science we may mention the names of

Klein, Le Verrier, Lister, Mendeléeff, and (Sir John) Murray. A great many of the graduates were Fellows of the Society of Antiquaries; for example, the Earl of Crawford, F.R.S., the founder of Dunecht Observatory, who went to Mauritius to observe the transit of Venus in 1874. Others who travelled to study happenings far from Cambridge include James Losh, who went to Paris to study the French Revolution and whose life was saved by Marat, formerly a veterinary surgeon in Newcastle; also three war correspondents—Kinglater for the Crimean War, Lockhart for the Franco-Prussian War, and E. F. Knight, a war correspondent in some dozen campaigns.

Various forms of sport and athletics figure among the records: the Hon. Ian Keith-Falconer, the most famous cyclist in the 'eighties, "Black" Morgan, who was the first (with Leslie Stephen) to climb the Jungfraujoch, F. E. Lacey, secretary of the M.C.C., Jack Mytton, the famous horseman, the Hon. George Lambton, trainer of many winners in classic races, John McGregor, of the 'Rob Roy' canoe, John Mackinnon, who played for England against Australia in 1879 and was presented with a bat by his clansmen on his ninety-eighth birthday, and we may add C. F. L'Oste, who went up in an aeroplane on his 103rd birthday, at which age he had never consulted a doctor.

In conclusion, a few names may be mentioned for the human touches in their biographies. W. J. Locke, the novelist, started as a graduate in mathematics, "an utterly futile and inhuman subject". John Mortlock was nine times Mayor of Cambridge. In contrast to J. C. Neild, a miser who left £500,000 to Queen Victoria, was Walter Scott Lockhart, described by his father as a "human financial sieve". Others who earned nicknames were John Lupton, "the pocket Hercules", Richard Martin, "Humanity Martin", H. H. Norris, "the Bishop-maker". Edward Meade-Waldo was one of the very few trained naturalists who claimed to have seen a sea-serpent, Sir William Molesworth, Bart., was sent down for challenging his tutor to a duel, and Edward Maitland claimed to have been previously Marcus Aurelius and St. John the Evangelist, "hence the mention of boiling oil was inexpressibly painful to him".

THE RODA NILOMETER

Le Mikyâs ou Nilomètre de l'Ile de Rodah

Par Kamel Osman Ghaleb Pasha. (Mémoires présentés à l'Institut d'Égypte, Tome 54.) Pp. xvi+182+46 plates. (Le Caire: Imprimerie de l'Institut Française, 1951.)

This book gives a detailed description and history of the Roda Nilometer or river gauge, with an account of the extensive repairs and restoration undertaken in 1938.

The author was officially in charge of the gauge for many years as inspector-general of irrigation in Upper Egypt and later as under-secretary of state in the Ministry of Public Works, from which he retired some years ago. It was owing to his efforts that the very thorough restoration of the gauge, estimated to cost about £36,000, was carried out under his supervision.

The Nilometer is situated on the southern edge of Cairo and consists of a large square well walled in stone with a marble column in the centre carrying a scale divided in cubits, and is connected with the river by subterranean passages. It was built about A.D. 861 and succeeded earlier gauges near the same spot, and a still earlier one some miles upstream near Helwan. Records of flood and low-stage levels on these gauges have come down to us beginning in A.D. 622, twenty years before the Arab invasion of Egypt. There have been Nilometers from very early times; but very little information about river-levels can be derived from those, other than that at Roda, which is the most important of all. It was in charge of an official, the Sheikh el Mikyas, whose duty it was to observe the water-level and in flood-time announce to public criers daily the amounts by which the river had risen. If the flood did not reach a certain level much land would go unwatered and there would be famine. At a certain higher level irrigation was assured; and also the taxes to the government. From the building of the present Nilometer until recent times the post of Sheikh el Mikyas has remained in the same family, and the last holder, who died in 1947, inherited the post through his grandmother, who was of the original family—surely a record for length of tenure of an official post in one family.

The book describes very fully the construction of the Nilometer and the changes in it which have taken place, including the recent restoration. In this the marble pillar was removed and the well was cleared of silt right to the bottom. This clearance uncovered work which was previously unknown and revealed the doubtful nature of the foundations. In order to preserve the Nilometer it was necessary to place a solid floor underneath it and surround the well with concrete. The well is now dry and cut off from the river, so the Nilometer should remain as an ancient monument for an indefinite time. The Nilometer has not been in use since 1887, and the river-levels have been observed on a metric gauge near by on the river wall.

Many excellent plates show the details of construction of the Nilometer and the discoveries made during the recent restoration. The author has collected a great mass of references to the Nilometer from the writings of old Arab scholars and of medieval and modern visitors to Egypt. The work of doing this must have been immense. This leads to what is perhaps the most important part of the book, the discussion of the recorded levels. The earliest records of gauge readings are lists compiled in the fifteenth century by three Arab writers; but the sources from which they were derived are unknown. These end with the year A.D. 1470, and after that the sources are a number of writings by Arabs and foreign travellers, and the records are much less complete. In relating these to present-day levels there are many difficulties due to the use by the chroniclers of the Moslem year, which is lunar, and, more important, the various repairs and changes which have been made to the column. In view of the researches of Ghaleb Pasha it will be necessary to revise the list of readings converted to a metric scale, which has been used in all investigations of the past forty years. This will affect the numerical values but not the most important conclusions derived from previous studies of the records. Taking a general view one may say that although the recorded readings contain many sources of error, and naturally have not the precision of modern observations, nevertheless they are probably as reliable as statistics collected to-day about less well-defined phenomena such as health or social conditions. They can be used with suitable precautions for such investigations as the search for periodicities or the probability of occurrence of high or low floods.

Ghaleb Pasha is to be congratulated on having collected and published this great mass of information relating to the Nilometer.

UNIVERSITIES OF THE BRITISH COMMONWEALTH

The Yearbook of the Universities of the Commonwealth, 1952

(Published for the Association of Universities of the British Commonwealth.) Twenty-ninth Issue. Pp. xxxii+1661. (London: G. Bell and Sons, Ltd., 1952.) 42s. net.

THE "Yearbook" of the Association of Universities of the British Commonwealth has established itself as a standard work of reference on both general and specific academic matters pertaining to the countries of the British Commonwealth, and such a comprehensive single volume is invaluable not only for universities and colleges but also for government departments, business houses, clubs, schools, libraries and the public generally. It is, in fact, the principal publication of the Association; but it is important to note that it covers Commonwealth university institutions and does not confine itself merely to member institutions of the Association.

This twenty-ninth edition is the largest ever published. The "General Information" sections of most university entries have been expanded, and four new appendixes have been added dealing respectively with United Kingdom degree abbreviations, Commonwealth studies in the United Kingdom, international university organizations, and a select bibliography of books on university topics. A further innovation is an introductory account of more than three pages in the section on the British Colonies, which has been prepared by the secretary of the Inter-University Council for Higher Education in the Colonies. Other changes, recorded for the first time in this edition, are as follows: Rhodes University College and Potchefstroom University College for Christian Higher Education, respectively, become Universities of the same name; entries are recorded for the three Indian Universities of Gujarat, Karnatak and Roorkee, and in Pakistan for the University of Peshawar; and entries are recorded for two additional Colleges recognized by the National Conference of Canadian Universities, namely, Carleton College and the Royal Military College of Canada. Finally, this edition now incorporates a date at the head of each university entry showing the time at which the information relating to the entry was compiled; this is certainly a very welcome piece of information.

The general contents of the book follow much the same lines as the previous edition. After a general introduction, the various universities and university colleges of the Commonwealth are listed, starting with the United Kingdom, then each Dominion in turn, and finally the Colonies. This section covers four-fifths of the book; there are the lists of staff (about 25,000 names), general information on each institution and events during the past year. The remaining part of the book consists of ten appendixes, an index of names and a general index. The appendixes cover respectively the following topics: qualifications for admission to a first-degree course in a British university; postgraduate awards tenable in the United Kingdom; postgraduate awards tenable overseas; students from other countries in British universities; degree abbreviations (United Kingdom only); Commonwealth studies in the United Kingdom; universities of the Republic of Ireland; Anglo-American academic relations; international university organizations; and a short bibliography.

A NATURAL HISTORY OF BACTERIA

Bacteria

By Dr. K. A. Bisset, assisted by F. W. Moore. Pp. viii+123. (Edinburgh and London: E. and S. Livingstone, Ltd., 1952.) 20s. net.

THE ancestral tree of bacteria that Dr. Bisset has drawn is based primarily on morphology; but, as he says in his preface, "it is in reasonable accordance with the parallel conception of evolution by loss of synthetic power". He postulates that the simple cell from which others have evolved is spiral in shape and aquatic in habitat; progress has occurred with an ability to survive in a terrestrial environment, and the development of a reproductive process that relies on airborne spread. Primitive bacteria are Gram-negative; evolution is shown in the development of the Gram-positive state. Starting with the simple spiral-shaped cells, the tree has four main branches. The first includes the Gram-negative rods and specialized aquatic forms; the second the chain-forming Gram-positive spheres and rods; the third those Gram-positive cells with a branching habit; and the fourth the order Flexibacteriales. Between the second and third branches are the packet-forming cocci. In more formal terms the class Bacteria is divided into four orders: Eubacteriales, Actinomycetales, Streptomycetales and Flexibacteriales; of these, Eubacteriales forms the first two branches of the ancestral tree; the second and third orders form the third branch.

Ordinary morphological characters only divide microscopic organisms such as bacteria into a limited number of groups of ordinal or family rank; further subdivisions into genera and species are usually made on physiological differences. Dr. Bisset has applied his work on the cytology of bacteria to the problem and has made use of finer differences in cell structure in his outline classification. This has both advantages and disadvantages: it takes morphology to a lower rank, but it demands unfamiliar, though not difficult, techniques of the systematist. The result is a classification with which few would quarrel except on points of detail.

In a book of this size it is impossible for the author to do justice to his ideas on the classification of so large a group as the bacteria, and many of the chapters are too brief to be highly informative. There is unfortunately only a brief reference to his interesting and controversial finding that strains of *Rhizobium* species from wild legumes produce resistant endospores; in this the strains differ from the better-known species which grow in symbiosis with cultivated crops. The development of his thesis that the

Rhizobia are related to the *Bacillus polymyxa* group would have made most interesting reading. Two often repeated misstatements that seem to owe their survival to plagiarism should be corrected in a later edition; they are the reputed decolorization of *Mycobacterium smegmatis* by alcohol, and that sporing bacilli are among the commonest airborne contaminants, a statement disproved by day-to-day experience in the laboratory and by air sampling.

In this book Dr. Bisset has given us the hors d'œuvres; we now look forward to a more substantial meal in the form of a fully documented manual on the natural history of bacteria.

ENZYME SYSTEMS

Enzymes and Enzyme Systems

Their State in Nature. Edited by John T. Edsall. (Memoirs of the University Laboratory of Physical Chemistry related to Medicine and Public Health, Harvard University, No. 1.) Pp. xiii+146. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1951.) 18*s.* net.

THIS volume is the first of a series of memoirs of the University Laboratory of Physical Chemistry related to Medicine and Public Health, Harvard University, and is a record of a symposium held in July 1949 on the state and nature of proteins and protein enzymes. It is only twenty-five years since J. B. Summer crystallized the first enzyme, urease, and demonstrated its protein nature. Since then a considerable number of enzymes have been crystallized, and, as Prof. J. T. Edsall remarks in the preface, "the generalization—'no enzyme without protein'—appears established as one of the most widely based inductive rules in the field of biochemistry". There is no doubt that very large numbers of protein enzymes occur in Nature and that in numerous cases they can be obtained in a relatively pure and crystalline state in which they can be studied as chemical individuals. Something having been found about the individual enzymes, the question arises: How are they assembled and co-ordinated in the cells so that long series of chemical changes are brought about so smoothly? This volume provides an excellent review of recent progress in this second stage of the study of enzyme function.

The notable progress made in recent years in the study of the enzyme activities of isolated mitochondria is the subject of the first two papers. A. L. Lehninger discusses the respiratory activity of rat-liver mitochondria, and D. E. Green the enzymes which are responsible for the citric acid cycle of reactions. The next group of papers deals with the mechanisms of enzyme reactions. E. L. Smith discusses the specificity of proteolytic enzymes—in particular those peptidases which require metal ions such as manganese or cobalt for their activity—and makes the interesting hypothesis that the metal ion is necessary to complete the bridge between the enzyme and the substrate peptide. A. C. Maehly describes the separation of an enzyme, the peroxidase of horseradish, into its component parts and its resynthesis from these parts. B. Chance discusses the reactions of ferrocytochrome-*c* with peroxidases. In the final paper E. J. Cohn, D. M. Surgenor and M. J. Hunter summarize the results of the very extensive researches on the separation of blood plasma proteins and of liver proteins, which have been carried out during the past ten or twelve years in the Harvard Laboratory. These researches are remarkable for the variety of new technical methods of protein separations which have been devised.

Altogether, this small book provides a very valuable introduction to recent work on complex enzyme systems and, as such, will be widely read.

J. A. V. BUTLER

BIOLOGY OF HOT SPRINGS

Grundriss zu einer Balneobiologie der Thermen

Von Prof. Vale Vouk. (Lehrbücher und Monographien aus dem Gebiete der exakten Wissenschaften: Reihe der experimentellen Biologie, Band 5.) Pp. 88. (Basel: Verlag Birkhäuser, 1950.) 11.50 Swiss francs.

THIS is a welcome addition to the well-known series of scientific text-books and monographs issued by Verlag Birkhäuser. The physical and chemical properties of natural waters, particularly thermal springs, and also their clinical effects, have received a considerable amount of attention and have formed, separately and in conjunction, the subjects of systematic reviews. While there are on record numerous observations on different forms of life occurring in hot springs and on the species present in different localities, the present monograph is, as far as the reviewer is aware, the first attempt to bring them all together and deal with the specialized ecology of this environment and the various problems associated with it in a systematic manner. It is therefore of considerable interest and may have importance in the practical field.

Thermal waters have been defined as having a more-or-less constant temperature above the average annual temperature of their surroundings; but, as is pointed out, this is not satisfactory from the biological point of view. In arctic or alpine situations this might easily mean that the temperature would be a normal one in lower latitudes or altitudes. Similarly, the differentiation of thermal waters with reference to the temperature of the human body leaves something to be desired. Prof. Vale Vouk proposes a classification based on the types of living organisms present. His grouping is: chliarotherm, 18°–28° C.; eutherm, 28°–44° C.; akrotherm, 44°–65° C.; and hypotherm 65° C. and above. Thus, for example, the only organisms in the last group are Bacteria and Cyanophyceæ, and it is noteworthy that some members of each of these categories can live at temperatures a little above 85° C.; again, no fish or amphibians are known above the eutherm.

Temperature is not the only ecological factor affecting life in thermal waters, for, *inter alia*, there is the question of the nature and concentration of the chemical substances they contain, and these vary with the provenance of the waters. Thus, while the genus *Mastigopus* is cosmopolitan in distribution, it is as a rule confined to akrotherm waters with a limited concentration of mineral salts. These and other peculiarities affecting living organisms, including the 'Fervor effect' of thermal waters, are adequately discussed. The book is well printed and illustrated, furnished with an index and good bibliography, and provides an adequate summary of the present state of our knowledge of the biology of thermal waters.

LEONARDO DA VINCI, ARTIST AND MAN OF SCIENCE (1452–1519)

By Dr. A. TINDELL HOPWOOD
British Museum (Natural History)

THE Quincentenary Exhibition in the Diploma Gallery of the Royal Academy throughout the summer is designed to illustrate Leonardo's many interests by means of his own works, particularly his drawings and manuscripts. Emphasis on the drawings was inevitable, for the finest collection of them in the world is that in the Royal Library, Windsor, whereas of the eighteen surviving paintings only one, the "Madonna of the Rocks", is in Great Britain. There is no need to describe the genesis of the Exhibition, or to name the owners (Her Majesty the Queen at their head) who have so generously lent their treasures; this is done in the catalogue, another of those masterpieces of concise scholarship one has come to expect as of right whenever the Academy holds a special exhibition.

The name Leonardo da Vinci is familiar to millions who have never seen any of the original drawings and paintings. For most of them he is the painter of "Mona Lisa" and "The Last Supper", or else a scientist and inventor, born before his time, who made his notes in mirror-writing for fear of the Inquisition. This last point is almost certainly a myth arising from religious prejudices. That Leonardo was left-handed his drawings make plain, and the natural tendency of some left-handed subjects to write from right to left, holding the pencil in the left hand as Vasari and others said that Leonardo did, is sufficient explanation. To others, more widely read, Leonardo means many different things, so universal was his genius; yet, were one to be asked what his achievement was, it would be difficult to give a concise answer. Painter, sculptor and architect; anatomist, rhymester and engineer; herbalist, musician and dandy; he was at once all these and more. None the less, little of his work survives outside note-books and drawings; neither do the accounts of those who knew him, nor those of the following generation, suggest that he ever completed so much as his younger contemporaries Michelangelo (b. 1475) and Raphael (b. 1483).

Why this should have been remains uncertain, but the ceaseless questing of his intellect may well have been the cause. Vasari, who wrote nearly thirty years after the death of Leonardo, suggested that little was finished because so much fell short of the master's aim: he also quoted the remark of Leo X, "This man will never do anything, for he begins to think of the end before the beginning". Another pointer in the same direction occurs in a letter dated April 4, 1504, from Fra Pietro da Novelara to Isabella d'Este, reporting that Leonardo's "mathematical experiments have made painting so distasteful to him that he cannot even bear to take up a brush"; and, in another letter only four days later, "Leonardo's life is changeful and uncertain; it is thought that he lives only for the day. . . . He is entirely wrapped up in geometry and has no patience for painting".

Primarily his fame rested and still rests on his drawings and paintings; his notebooks were not deciphered until long after his death. So far as sculpture is concerned, the great clay horse for the Sforza monument was never cast and was destroyed by the French archers when they entered Milan in 1499: this was his most ambitious piece. For the rest, some small works in marble and terra-cotta from the workshop of Verocchio have been attributed to Leonardo in his young days, as well as two small bronze horses, one in Budapest and one in the present exhibition, and three life-sized bronze figures over the door of the Baptistry in Florence. These last, by Rustici, are supposed to owe much to Leonardo's assistance, although, as Vasari recorded, "nothing definite is known".

While he worked at the model for the Sforza monument, Leonardo studied the anatomy of the horse and compiled a note-book of his observations. The book was lost when the French entered Milan; but some drawings made at that time survived and are now at Windsor. At this same period he also dissected a bear, and on various occasions made drawings of dissections of frogs, birds, monkeys, and even lions. His chief interest, however, was in the anatomy of man, "who ranks among animals as first of the beasts" (in this phrase he anticipated Linnæus by two hundred and fifty years), and the fortunate circumstance that by far the greater number of his anatomical studies is now at Windsor has enabled this aspect of his scientific work to be displayed in remarkable detail. Fully to describe the drawings is not possible; they show that he realized that a horse walks on the tips of its toes, that there are similar structures in the legs of frogs and men, and that he not only described the antrum of Highmore, but also the right and left cardiac atria, the cerebral ventricles, of which he prepared casts in wax, and the valves of the heart. The full extent of these studies, at which he worked for a while with Marcantonio della Torre (1482–1512), professor of anatomy at Padua, is indicated by his statement to Cardinal Luigi d'Aragona in October 1517, only eighteen months before he died, that he had dissected more than thirty bodies of all ages, both male and female.

With so much anatomical work to his credit, one might have thought that Leonardo's time was fully occupied, but it was not; of the more than five thousand pages of notes and sketches still in existence, a large number is concerned with engineering projects, machines and scientific instruments. Some of the sketches illustrate his own inventions, others are the earliest known representation of a given object, and yet others are of machines invented before his day for which he had devised improvements. All these aspects are illustrated in this exhibition, and their interest is greatly enhanced by means of a number of models prepared in the workshops of the Science Museum from his notes and drawings.

Among the models are an *N*-girder bridge, a helicopter designed to have a radius of 14 ft., a parachute, a screw-cutting machine of advanced design, and machines for grinding plane and concave mirrors. These are by no means all. One drawing shows the earliest known observation of magnetic dip, another is of articulated driving chains, which he may have invented, and yet another represents the first known use of a pendulum to regulate a clock.

Lastly, there is a contrivance whereby a "weight jerks violently upward the feet of a sleeper, who is thus awakened and goes about his business". Whether this was seriously meant one cannot say; many similar devices are familiar to students of the history of inventions. The particular interest of Leonardo's apparatus is that it is an early example of a relay mechanism.

Concerning the paintings, it would be difficult to add anything to the notes in the catalogue, particularly as they include selected references to the vast literature that has grown up around the subject; but the smile of Mona Lisa, often called mysterious, is a small point of interest unmentioned in the notes. A like smile, so faint as to be barely perceptible, is to be seen in "La Belle Ferronnière" (Louvre), and again, a little stronger, in the "Lady with an Ermine" (Warsaw, Czartoryski Museum). This smirk annoys some, who point out that the women in religious pictures smile in a normal manner (cf. "The Virgin and Child with St. Anne and St. John": No. 109). It should be borne in mind, however, that Leonardo was the greatest painter of his time, and that his sitters, besides being paintable, were wealthy and fashionable. Now the fashionable smile of the ladies of the Renaissance was that painted by Leonardo; in their books of etiquette it was laid down that they should close the mouth at the right corner and open it on the left as though they were smiling secretly. But the fashionable smile of Mona Lisa was not suitable for sacred art; neither, so far as I am aware, did Leonardo ever depict it there. We have Vasari's authority that while Leonardo was painting Mona Lisa, "he engaged people to play and sing and jesters to keep her merry. . . . This figure . . . had such a pleasant smile that it seemed divine rather than human, and was considered marvellous, an exact copy of Nature". The fame of the smile has not diminished after four centuries and a half; but, "an exact copy of Nature"? How that phrase illuminates the gulf extending between the High Renaissance and the present.

THE BRITISH CONTRIBUTION TO TELEVISION

During April 28–May 3, the Institution of Electrical Engineers held a convention on "The British Contribution to Television", which was attended by more than 1,300 registered members, including 137 delegates from twenty-one different countries. The programme comprised ten sessions, at which more than eighty technical papers were presented and discussed, and a number of visits to such places as the B.B.C. television stations and studios, the Post Office Research Station and some dozen firms in the radio industry. A few social gatherings were also arranged, including a Television Ball and Dinner at Grosvenor House, London.

The convention was opened by the Right Hon. Lord Woolton, who surveyed briefly the development of television in Great Britain, starting from the suggestion put forward in 1908 by Mr. A. A. Campbell Swinton to use beams of cathode rays to convert the rapid variations of light and shade into electric impulses at one end, and to reverse the process at the other end of the system. He referred to the facts that the first public television service in the world started in London in 1936; and that the completion of the present plan of installing five high-power and five medium-power stations in Britain will make the television service available to about 88 per cent of the population of the United Kingdom. While we can scarcely expect to emulate the achievements of the United States in their spectacular development of television during the past five years or so, it is gratifying to observe that the radio industry in Britain has taken full advantage of the opportunities provided by the corresponding development here. Many firms must now have, in production, cathode ray tubes and other components assembled in television receivers, on a scale which would have been deemed impracticable a few years ago.

After a brief expression of thanks by Sir John Hacking, president of the Institution, who also welcomed Dr. Donald Sinclair, president of the Institute of Radio Engineers, New York, and other distinguished visitors and guests, an address on "Television Development" was presented by Sir Noel Ashbridge, then the director of technical services of the British Broadcasting Corporation. He traced the growth of the television service in Great Britain from the early experiments of J. L. Baird, with a low-definition system of 30 lines per frame and 12½ frames per sec., to the adoption in 1937 of the system developed by the Marconi-E.M.I. Co., using the technical standards of 405 lines per picture, 25 pictures (50 frames) per sec. with double interlaced scanning and positive modulation. While these standards are practically identical with those in use to-day, there has been much discussion at international committees during the past two years on the relative merits of this and other standards, differing mainly in the use of a greater number of lines per picture. As Sir Noel pointed out, for any improvement to be obtained by the use of more scanning lines, the band-width available at every point in the chain of transmission and reception must be increased correspondingly, with increase in costs all round. If this increased band-width is not available, a worse picture may result than that given by the present system using a smaller number of lines. It is greatly to be regretted that little progress has been made towards internationally agreed standards for television services; and there are, so far, four different specifications for black-and-white television in use, or shortly to be used, for broadcasting.

Looking to the future, Sir Noel said that colour is almost certain to be the most spectacular development in the next few years, and there are two systems sufficiently developed in the United States to merit serious and immediate consideration. No system has, however, been very definitely established on a public-service basis; but it is certain that the costs will be greater than with the black-and-white system in all respects, namely, programme production, technical operation and capital cost. While the use of colour may not be justified in all cases, there is no reason why colour television should not in the end give truer reproduction than colour films have in the past.

Reference was also made to the possibilities of stereoscopic television, with or without colour, and to the other applications of television, such as surgery, whereby a considerable number of people can witness a demonstration under conditions in which limited accommodation would make this impracticable otherwise.

At the second session of the convention, a broad historical review of the development of television was presented by Messrs. C. R. M. Garratt and A. H. Mumford. The history of television may be said to date from the observations, made by Becquerel in 1839, that when two electrodes are immersed in a suitable electrolyte and illuminated by a beam, an electromotive force is generated between the electrodes. The next stage was the discovery by Willoughby Smith in 1873 of the effect of light on the resistance of selenium. This discovery had no immediate sequel, but the era of stimulated progress which followed Bell's invention of the telephone in 1875 provided the background for numerous ideas for 'seeing by electricity'. Many of the resulting inventions were impracticable, chiefly because other discoveries and developments essential to the realization of the main ideas had not been made. From these beginnings, this paper traced the development of television following the suggestion of Campbell Swinton referred to above, and the introduction of the thermionic valve into radio practice. The presentation of the paper was accompanied by a demonstration of the mechanical system of television reception developed by Baird and used in the early experiments of the B.B.C.

The third session was introduced by Mr. D. C. Birkinshaw with a paper entitled "Television Programme Origination: the Engineering Technique". This paper, which was supported by fourteen others, surveyed the development of the engineering techniques associated with the origination of television programmes in Great Britain. Both studio and outside broadcast equipment were dealt with; much detailed design information from experienced authors is contained in these papers.

At the following session, Mr. P. A. T. Bevan reviewed the television transmitting scheme by which the British Broadcasting Corporation hopes to serve the greater part of the population of the United Kingdom. The basic factors underlying the choice of the scheme are discussed in the paper, together with the arrangements for dividing the available frequency-band into five separate channels. The general design of the complete equipment used at the transmitting stations is described with particular reference to the different types of vision and sound transmitters. The four supporting papers describe some of the special equipment features, including the aerial systems, in greater detail.

A survey of British research on wave propagation with particular reference to television was presented at the fifth session by Dr. R. L. Smith-Rose, and his remarks were amplified in four supporting papers. In this review emphasis was placed on the fact that the planning and successful operation of a national television service involves a somewhat detailed understanding of the mode of propagation of the radio waves concerned. For the service to be successful, a satisfactory ratio of the wanted signal to the prevailing noise or other interfering signals must be established within the reception area of each transmitting station. In addition, in view of the necessity of operating two or more stations in the same frequency-channel, a statistical knowledge of the propagation of the waves concerned to considerable distances is necessary in order to avoid mutual interference of the different transmitting stations. Furthermore, the use of radio links at extremely high frequencies for the exchange of programmes between stations involves a knowledge of the vagaries of the propagation of the very short waves concerned under varying atmospheric conditions. The papers presented at this session contain the results of many years work in this field, and form a basis of fundamental knowledge which has enabled the planning and establishment of a television service to be carried out so successfully in Britain.

With two introductory papers and eighteen supporting contributions, the next session dealt with point-to-point transmission. Dr. A. R. A. Rendall and Mr. W. N. Anderson described the arrangements used for temporary linkages for outside broadcasting purposes; while Mr. H. Faulkner spoke on permanent point-to-point links for relaying television programmes between transmitting stations. The object of these links is to provide a reliable system of transmitting vision signals involving a band-width of 3 Mc./s. over which the electrical characteristics are uniform and stable to a high degree. Experience in Great Britain has shown that excellent results can be obtained either by coaxial cable or by radio transmission, so that the choice between the two systems is largely a question of economics. The present advantage appears to be with the cable links on combined television and telephony routes; but, when radio links have been developed for the simultaneous transmission of television and multi-channel telephony, this advantage will be nullified. An item of interest in this connexion is that the travelling-wave tube, produced in Great Britain during the War, has found its first commercial application in the radio link between Manchester and Edinburgh. At the working frequency of 4,000 Mc./s., its high amplification and low noise-factor render an intermediate-frequency amplifier unnecessary and this reduces the overall cost of the link. The supporting papers describe in detail some of these radio and cable links and the associated equipment and testing apparatus.

The seventh session, on "Industrial Television", was outstanding in so far as the presentation was concerned. By the aid of a television link and a projection-type receiver and large screen, the authors introduced their papers from the lecture hall of the Institution of Civil Engineers, while the audience of more than six hundred watched in the adjacent Great Hall. In his survey paper, Dr. R. C. G. Williams pointed out that Great Britain has pioneered in industrial television no less than for broadcasting. Apart from the use of television for education and training and similar 'large-screen' work, an important application is to take advantage of the 'extension eye' principle in such fields as underwater television, the demonstration of surgical operations and the observation of dangerous processes. Among the eight supporting papers was one by Mr. F. Roberts and Prof. J. Z. Young entitled "The Flying-Spot Microscope". In the presentation of this, the authors demonstrated how the apparatus could give an accurate count of the thousands of minute nerve endings in a human nerve trunk, of which they showed a cross-section larger than had ever been seen before as a result of the magnification of more than half a million times with the large-screen equipment.

The next two sessions of the convention dealt in considerable detail with the problems of television reception, and especially with the design and construction of receivers, and the valves and cathode-ray tubes for use therein. In addition to the two survey papers, there were fifteen supporting papers which had been prepared by experts in the various phases of the reception of television broadcasting.

In the tenth and final session, Mr. L. C. Jesty dealt with "Television as a Communications Problem", and laid stress on the need for conserving ether space in the transmission of television signals. This phase of the subject will become of enhanced importance when the possibility of colour television is discussed, and also in connexion with the relaying of programmes over very great distances. Ten supporting papers contribute much detailed information to this question, and two of these deal with some fundamental aspects of colour television of both a subjective and objective nature.

There is no doubt that the holding of this convention brought together a large amount of detailed and expert technical knowledge on the various aspects of television described above; and this knowledge will prove very valuable to those responsible for the future development of television everywhere. The complete proceedings of the convention, containing the addresses, the full text of all the papers and reports of the discussions, will be published in four issues (Nos. 17–20 inclusive) of a special volume of the *Proceedings of the Institution of Electrical Engineers*, Part III A. The first of these special issues is expected to appear shortly. Those requiring copies should apply to the Institution of Electrical Engineers, Savoy Place, London, W.C.2, from whom details of the contents and subscription-rates may be obtained. R. L. Smith-Rose

PRINCIPLES GOVERNING THE AMOUNT OF EXPERIMENTATION IN DEVELOPMENTAL WORK

By Dr. F. YATES, F.R.S.

Rothamsted Experimental Station

GREAT BRITAIN has lagged badly behind the United States in the practical utilization of scientific discoveries. This is reflected in the demand for men of science in the two countries. The recently published Fifth Annual Report of the Advisory Council on Scientific Policy[1], for example, directs attention to the fact that the United States is turning out nearly three times as many men of science in proportion to the labour force as Great Britain is, and is planning further increases, particularly at the higher level. In part this lag in putting scientific discoveries to practical use is attributable to our neglect of the experiments and tests which are necessary in developmental work. These experiments differ markedly from the laboratory experiments required in pure scientific research, since their main function is to establish empirical rules of operation which are applicable under practical conditions. With the present drive for economy there is serious danger that even such facilities as are available for experimental work of this kind will be curtailed or not used to full advantage. It is therefore important to stress that such curtailment will result in much more substantial and immediate losses through failure to determine the best practices. Developmental work must be expanded, not contracted, if we are to survive.

It is perhaps somewhat remarkable that no very precise consideration appears to have been given to the expenditure that is justifiable in developmental work. Instead, experimenters have tended to rely on their intuitive judgment on the accuracy that should be aimed at, and are frequently influenced in this judgment by the demands, often misplaced, for economy. In its essentials the problem is very similar to that of deciding the accuracy required in a sample survey. For this latter problem I put forward the general principle that the accuracy should be such that the sum of the cost of the survey and the expected losses due to errors in the results should be minimized[2]. The same principle can be applied to experimental work. It is indeed here more widely applicable, since it is usually easier in experimental work to assess the losses due to errors of a given magnitude in the results.

In experimental work, however, we have at the outset to consider the type of results that are likely to emerge and the way in which they will be used. In the case of a treatment of the all-or-nothing type we may simply require a decision on whether or not to apply the treatment uniformly to the whole of the material, or to certain categories, already defined, of the material; or we may hope that the experiments themselves will reveal a way of classifying the material into categories for some of which the treatment will be profitable and for others unprofitable. Similarly, in the case of a quantitative treatment, we may require only to determine what uniform level of treatment gives the greatest economic return, or we may hope to divide the material into categories for which different levels of treatment will be most economic, or find some quantitative characteristic of the material which is correlated with the most economic level.

If the discovery of appropriate categories for non-uniform treatment is the aim, more elaborate experiments will often be required. We may also be prepared to sacrifice some of the smaller gains resulting from pushing the simpler type of investigation to its economic limit in the hope of obtaining the much larger gains which will result from the effective use of differential levels of treatment. For the moment, however, we will leave aside these more difficult problems, and consider the simple case in which the whole of the material is to be treated uniformly.

When a decision whether or not to apply a treatment is required application of the above principle is complicated, and we shall not discuss the matter further here. The problem is probably only soluble in terms of fiducial probability, using the sequential approach, and then with difficulty. It is essentially that propounded by Wald in his "Statistical Decision Functions"[3]. When the most economic level has to be determined, on the other hand, the solution is very simple, and reveals a number of features of general interest.

At the outset it will be well to make clear exactly what is meant by the concept of expected loss due to errors in the results. Consider, for example, the question of the use of fertilizer on an agricultural crop. If the whole of the crop is to be treated alike, the most economic level of dressing, which for convenience we will call the *optimum* level, will be the level at which the cost of a further small increment of dressing exactly equals the value of the resultant average increment in response. In the neighbourhood of the optimum the net loss due to departure from the optimum will in general be proportional to the square of the difference of the actual dressing from the optimum. If, therefore, instead of the optimum dressing $\hat{x}$ we apply a dressing $\hat{x} \pm \delta x$ there will be a net loss of $\lambda(\delta x)^2$ per acre, where λ is some constant.

If $\hat{x}$ is estimated by means of a set of experiments, and the estimate is subject to an error variance $V(\hat{x})$, then the average value of $(\delta x)^2$ over a large number of such sets of experiments will be $V(\hat{x})$. The expected loss due to error in the optimum will therefore be $\lambda V(\hat{x})$. The actual loss may of course be less or greater than the expected loss. An inaccurate set of experiments, for example, may by chance give the correct answer.

If, therefore, the cost C, apart from any 'overhead' or constant component, of an amount q of experimentation is cq, and the error variance of the estimate of the optimum level determined from such experimentation is v/q, the expected loss L will be $\lambda Av/q$, where A is the amount of the material to be treated. We therefore have

$$C + L = cq + \lambda Av/q.$$

This is a minimum when

$$q = \sqrt{(\lambda Av/c)}.$$

In this case

$$C = L = \sqrt{(\lambda Avc)}.$$

In other words, ***the most economic amount of experimentation is that in which the cost of the experimentation apart from overheads is equal to the expectation of loss due to errors.***

If an amount A of material has to be treated each year for an indefinite period, and the experiments take a year to carry out, A must be replaced by A/r, where $100r$ is the interest rate. If constancy of conditions cannot be assumed indefinitely and it is decided to repeat the experiment after t years, then A is replaced by

$$\frac{A}{r}\left\{1 - \frac{1}{(1+r)^t}\right\}.$$

The net loss resulting from undertaking a fraction or multiple f of the most economic amount of experimentation is

$$(f + 1/f - 2)C.$$

If, for example, the cost, apart from overheads, of the most economic amount of experimentation is £4,000, the costs and losses when f has the values of 1, ½ and ¼ will be as follows:

f	Cost of experiments (C)	Expected loss (L)	Cost + loss ($C + L$)
1	£4,000	£4,000	£8,000
½	£2,000	£8,000	£10,000
¼	£1,000	£16,000	£17,000

This table can be looked on as giving the expected additional gains from additional amounts of experimentation in the neighbourhood of the most economic amount. The total gain from the experimentation as a whole cannot, of course, be assessed by this means. In the common case in which the application of the treatment cannot be risked without *some* experimentation, the total gain will be that due to the use of the treatment. This will often be large compared with the marginal gain in the neighbourhood of the most economic amount of experimentation. If, for example, the gain from using the treatment at the correct optimum level is £100,000, and overheads and preliminary fundamental scientific research are costed at £5,000, with other costs as above, the total and net gains will be as follows:

f	Research expenditure (C + £5,000)	Expected total gain (£100,000 − L)	Expected net gain
1	£9,000	£96,000	£87,000
½	£7,000	£92,000	£85,000
¼	£6,000	£84,000	£78,000

In other words, the return on the first £6,000 of research expenditure is £84,000, on the next £1,000 is £8,000, and on the next £2,000 is £4,000.

If, therefore, experimental resources are scarce there may be a case for not carrying out the full amount of experimentation that can be justified on economic grounds, since the returns on the last few incremental steps are relatively small, and it may therefore be possible to use the immediately available experimental resources more effectively on other problems. However, the experimentation which is required to determine an optimum for uniform treatment is often capable also, if properly planned, of providing a basis for differential treatment. If successful in this respect further large gains may accrue. Consequently, since gains must on the average result from increasing the experimentation to the most economic level for uniform treatment, even if no effective basis for differential treatment is found, there is every justification for building up an experimental organization which is capable of dealing with this volume of experimentation.

There is one further point which is often of considerable practical importance. In many types of experimentation it is somewhat difficult to ensure that experimental conditions fully conform to the conditions under which the treatment will be used in practice. If this is not the case a constant component of error, that is, a bias, will be introduced. An error of this kind will not be eliminated by increasing the amount of experimentation, nor will it be revealed by the variability of the experimental results. Although the gains resulting from increased experimentation will *on the average* be the same whether or not a bias exists, the elimination of the bias may result in much larger gains. Additional experimental effort may therefore in such cases be much better directed to the elimination, reduction or correction of the bias, rather than to the reduction of the relatively small random component of error. To effect this a radically different type of experiment may be required.

As an example of the application of the above principles to a practical situation we may consider the experimental work on the effect of fertilizers on sugar beet, a crop introduced into Britain after the First World War. The early recommendations were based on Continental experience, but after various unco-ordinated experiments had been carried out a co-ordinated series of factorial experiments was started in 1933 and continued to 1949 to test the responses to nitrogen, phosphate and potash. The average number of experiments was twenty-two per year, and the total annual cost, exclusive of overheads, was about £700 per annum at pre-war prices.

As an example of the practical value of these experiments it may be mentioned that the results obtained up to 1939 enabled confident recommendations to be made in 1940 on the manuring of sugar beet under war-time conditions[4]. It was recommended, for example, that a dressing of 0·7 cwt. nitrogen per acre would be optimal, in contrast to the dressing of 0·45 cwt. nitrogen which had previously been recommended[5], and which was, in fact, about optimum at the prices ruling prior to the War. The net gain resulting from the change from 0·45 cwt. nitrogen to 0·7 cwt. nitrogen was about 15*s*. per acre at 1940 prices. If this change were made on the whole of the sugar beet acreage the total net gain would be £300,000 per annum. The actual net gain was probably considerably larger, since under-manuring of sugar beet (and other crops) was common before the War.

The determination of the most economic number of experiments in a situation of this type is complicated, owing to the fact that there is an additional random component of variation in response from year to year due to variation in meteorological conditions, and there is also a possibility of long-term changes due to changes in agricultural conditions. Without going into details, which will be dealt with elsewhere, it may be stated that an analysis of the variation in the nitrogen responses indicates that as far as this fertilizer is concerned about sixty experiments per year, possibly falling to forty per year after the first few years, may be regarded as most economic. In view of the fact that many farmers do not as yet follow at all closely the recommendations emerging from such experiments, the programme can be regarded as about adequate for the simple function of determining optimum uniform dressings. Indeed, from this point of view, the most serious defect of the experiments was the fact that the selection of the sites was not fully random, so that appreciable biases may have been introduced into the results.

The experiments were, however, quite correctly undertaken with the additional and more ambitious aim of investigating possible differences in response on different soil types, and establishing relations between responses and chemical analyses of the soils. In the case of nitrogen, for example, it was confirmed that the responses to nitrogen on fen soils (constituting 10 per cent of the sugar beet acreage) were very small, and would not pay for the cost of nitrogenous fertilizer. This fact is still not fully appreciated by the farmers concerned, 85 per cent of whom, according to a 1945 survey of fertilizer practice, applied nitrogen averaging 0·3 cwt. nitrogen per acre. Omission of this nitrogen would save about £25,000 per annum at present prices, that is, about twenty times the annual cost of the experiments. Considerably larger gains may be expected from the better utilization of the differences in response to phosphate and potash on different soil types and their relations with the chemical analyses of soils. That there is room for substantial economies is obvious when it is realized that the total cost of fertilizers applied to sugar beet is of the order of £3 million per year. For these more ambitious objectives a larger number of experiments would certainly have been economic.

But if the experimental work on sugar beet must be judged to have been scarcely adequate for the purposes for which it was undertaken it is, in fact, the high-light of all experimental work on fertilizers in Great Britain. Sugar beet is the only crop on which any co-ordinated series of modern well-designed factorial experiments has been carried out and the only one for which there has been any attempt to secure a selection of fields for the experimental sites which would be reasonably representative of the whole of the land growing sugar beet. For no other crop is there any adequate series of experiments for which chemical analyses of the soils of the experimental sites have been made, or for which there are any adequate descriptions of these soils. On the more difficult questions of fertilizer practice, such as how to use fertilizers on grassland, and the residual values of phosphate and potash, the amount of co-ordinated experimental work is negligible.

If experimental work in agriculture is to be expanded to a more economic level it will, of course, require a complete reconstruction of the existing machinery for experiments. More work is required not only on fertilizers but also on the many other aspects of crop and livestock production that are capable of simple and exact investigation by empirical experiments. If properly organized, such activities need not interfere with more fundamental scientific research, since technicians rather than research workers are the main requirement. The principal functions of the research workers will be to determine what experiments are worth while, to see that they are properly planned, and to examine the results for relationships which are unknown or only suspected when the experiments are begun.

I have chosen an example from agriculture because this is the field with which I am most familiar, and because it can be demonstrated by the principles set out in this article that the amount of empirical experimentation is here entirely inadequate. The general principles enunciated are of wide application in many other fields, and in particular in many branches of industrial research. The technique of empirical experimentation on highly variable material is relatively new, depending in large part on statistical developments made by British workers during the past thirty years. We have yet to learn how to use this technique to the best advantage, but that it justifies wider and more thorough use there is no question.

OBITUARIES

Prof. H. A. D. Neville, C.B.E.

AGRICULTURAL education and the University of Reading have both suffered a heavy loss by the death on June 17 of Prof. H. A. D. Neville, emeritus professor of agricultural chemistry in the University of Reading.

Neville was born at Blackburn in 1880 and was educated at Queen Elizabeth's School and the Technical College, Blackburn, obtaining, from the latter institution, the degree of B.Sc. (London) as an external student. After a brief spell as demonstrator under Prof. W. J. Pope, at the Manchester College of Technology, he returned to Blackburn as lecturer and demonstrator under Dr. R. H. Pickard. From there he went, in 1906, to the County Laboratories at Chelmsford, and it was here that he made his first contacts with agricultural chemistry. In 1911 he proceeded to Cambridge to work with Prof. T. B. Wood and Prof. F. Gowland Hopkins; there he was in the midst of agricultural chemical teaching and research. August 1914 found him in the Royal Engineers. He rose to the rank of captain and was mentioned in dispatches. By 1917 he was carrying out research in the Munitions Investigation Department. Neville returned to Cambridge early in 1919, but by September of that year he was appointed to the chair of agricultural chemistry at University College, Reading. Within a year he was elected dean of the Faculty of Agriculture and Horticulture, and continued to hold these positions in the College, and later in the University, until he retired in 1947. In 1948 he was awarded the O.B.E.

In the early days, Neville worked with Pope and Pickard on problems chiefly concerned with the optical activity of a variety of organic compounds. However, his Cambridge days show a complete change of subject, and his researches there dealt with such matters as the fat of yeast and the mucilage of linseed; he was also joint author of a paper on the relative value of white and wholemeal bread. Neville was always described as an excellent analyst and research worker by those who knew him, and in some ways it is to be regretted that the turn of events at Reading led him into administration. Nevertheless, he was the guiding spirit behind the many excellent soil surveys which were carried out by members of his staff between 1925 and 1940.

What was lost to research was gained by the University and the Faculty, for Neville was a first-class administrator. He was one of a small body of men who guided the University College in those important years immediately before the granting of the charter in 1926, and he was the real architect of its Faculty of Agriculture and Horticulture.

The committees connected with university work and particularly with agricultural education on which Neville served are too numerous to mention here; but it was through these that he became known to, and respected by, a large number of people.

H. A. D. Neville was a wise administrator, an excellent teacher and a very good conversationalist; he is gone, but the Faculty of Agriculture and Horticulture of the University of Reading will ever be his monument. CYRIL TYLER

Dr. F. B. Pidduck

FREDERICK BERNARD PIDDUCK, whose body was found on July 1 on a Lakeland mountainside, had lived at Keswick after his retirement in 1950 from a long and distinguished career in scientific research and teaching at Oxford. Born on July 17, 1885, at Southport, he proceeded from Manchester Grammar School to Exeter College, Oxford, where he gained first-class honours both in mathematics and physics, and also the junior and senior mathematical University scholarships. He then studied for a short time at the Technische Hochschule, Charlottenburg. From 1907 he was a Research Fellow of the Queen's College, Oxford, whence in 1921 he became Fellow and Tutor of Corpus Christi College, where the rest of his official life was spent. During 1916–18 he rendered war service as a research officer in ballistics, with rank of captain, at Woolwich Arsenal, where his work gained official commendation. In 1923 he was awarded the D.Sc.(Oxford) for a thesis that included two important contributions to the kinetic theory of gases. In 1927 he became University reader, having previously been lecturer, in applied mathematics; this position he resigned in 1934. Electrical theory was one of his main interests, and he published two text-books on it, in 1916 and 1937, a technical treatise on currents in aerials and high-frequency networks (1946), and, with R. K. Sas, in 1947, an account of the M.K.S. system of electrical units, for which he was an enthusiast.

He was an extremely able mathematician, who preserved his intellectual originality and vigour to the end of his life. He wrote a series of important papers on the magnetron oscillator, and one of his last papers completes a theory of diffraction which he believed would ultimately take a fundamental place in optics. He was also a skilled experimenter, and long acted as senior demonstrator at the Electrical Laboratory, Oxford.

Active and athletic, Pidduck was an all-the-year-round swimmer, and an amateur photographer. He entered little into the life of his Colleges and University, and was apt to dwell on grievances. His reclusive habit unfortunately deprived his fellow workers of valuable contact with his able and wide-ranging mind, and may have contributed to what with some justification he felt to be an undue lack of public recognition of his notable achievements. One of his characteristics that he took trouble to conceal was his private generosity. S. C.

Colonel W. C. Devereux

BY the death on June 21 of Colonel W. C. Devereux, science has suffered a loss which is more serious than would normally be the case in the passing of an important and colourful industrial figure. For 'Dev', as he was universally called by his friends— and these included his work-people—combined success in industry with a real appreciation of the value of scientific and industrial research.

This was based not so much on philanthropy as on a knowledge that scientific research was commercially sound and indeed an essential basis for the new and expanding industry of light metals. After the First World War, during which he was superintendent of the first national aircraft factory, he developed the technique of forging light alloy pistons and was in frequent contact with Dr. W. Rosenhain and his team at the National Physical Laboratory in their work on *Y* alloy. The success of the forged piston in practice led to the formation in 1927 of High Duty Alloys, where the research laboratories, which were constantly expanding, were always an essential and integral part of the organization. Constantly in touch with the foundry and factory, the research laboratories none the less produced results of fundamental importance, as instanced by the work of Dr. L. Frommer on stress analysis by X-ray methods and on spectrographic analysis, and the studies of Dr. R. F. Hanstock and his collaborators on damping capacity.

On resigning from the office of chairman and managing director of High Duty Alloys in 1945, Colonel Devereux formed Almin, Ltd., and took the opportunity of founding the Fulmer Research Institute at Stoke Poges. His contacts with research and development in the United States during the Second World War had convinced him of the need in Great Britain for an organization for carrying out sponsored research to supplement the work of private industrial laboratories and co-operative research associations. The growth of that organization, which has more than doubled its staff (which now includes more than thirty graduates) and trebled its income, is an indication of the soundness of his judgment. Although confident of the continued success of the Institute, we cannot over-estimate the loss we have suffered in the dynamic and zestful personality of our late chairman, who quickly became a personal friend to those of us who had the privilege of working for him. E. A. G. LIDDIARD

NEWS and VIEWS

Chemistry at the Manchester College of Technology: Prof. H. N. Rydon

DR. H. N. RYDON, who has been appointed to the chair of chemistry at the Manchester College of Technology, succeeds Prof. J. Kenner, who has been made emeritus professor. Dr. Rydon was a student at the Imperial College of Science and Technology, London, where as a Royal Scholar he graduated with first-class honours in 1931. After a period of service on the academic staff at the Imperial College and at Birkbeck College, he was elected in 1937 by the Commissioners for the Exhibition of 1851 to a senior studentship, with which he proceeded to Oxford to continue his researches in organic chemistry. In 1939 he was awarded the Meldola Medal, a distinction reserved for younger chemists of exceptional promise; and in 1941 he was chosen as Harrison Memorial prizeman. In the meantime, Dr. Rydon had accepted a post at the Chemical Defence Experimental Station of the Ministry of Supply at Porton, whence in 1944 he was seconded to the Microbiological Research Department. Later, as a member of the scientific staff of the Medical Research Council Unit for Bacterial Chemistry, he worked at the Lister Institute. In 1947, however, he returned to academic work as reader in organic chemistry at Birkbeck College, University of London; in 1949 he became assistant professor and reader in organic chemistry at the Imperial College, where he has been responsible for the organization and general supervision of the advanced practical exercises in organic chemistry forming part of the new undergraduate course of study. In his earlier contributions to organic chemistry, Dr. Rydon participated in studies on olefinic acids which had been undertaken at the Imperial College by Prof. R. P. Linstead; later, he was associated with Sir Robert Robinson in investigations on the sterols; other researches have been concerned *inter alia* with the chemistry of the 2-chloroalkylamines, with the mechanism of the Michael reaction, with the constitution and synthesis of various organic compounds of natural origin, and especially with the biochemical aspects of bacterial growth and inhibition. Dr. Rydon's major interests at present are the chemical basis of chemotherapy, including the chemistry of peptides, and the organic chemistry of phosphorus.

Thermodynamics in Birmingham: Prof. F. K. Bannister

PROF. F. K. BANNISTER has been appointed to a newly created chair of thermodynamics in the Department of Mechanical Engineering in the University of Birmingham. The chair has been created in connexion with the organization of the new graduate school in thermodynamics, and Prof. Bannister will be in charge of this school under Prof. G. F. Mucklow, head of the Department of Mechanical Engineering. Prof. Bannister studied electrical engineering at the Burnley Municipal College and took his first degree in physics in the University of Leeds in 1930. He also holds a London external degree in mechanical engineering. He was a lecturer in mechanical engineering at Burnley Municipal College during 1937–40. In 1941 he was appointed lecturer in mechanical engineering in the University of Birmingham, and was granted the degree of Ph.D. in 1946 and became senior lecturer in the Department in the following year. He was appointed reader in thermodynamics in 1951. Prof. Bannister is well known for his work in thermodynamics, and in particular for his studies in the field of the transmission of pressure waves in gases within containing vessels and the application of these theoretical and experimental studies in such problems as arise in internal combustion engines. He was the joint author with Prof. G. F. Mucklow in 1948 of a paper entitled "Wave Action following Sudden Release of Compressed Gas from a Cylinder", which was awarded the Ackroyd Stuart Prize of the Institution of Mechanical Engineers. He has been closely associated with the Air Squadron at the University of Birmingham since its formation in 1941.

Zoology at Birkbeck College, London: Dr. W. S. Bullough

DR. W. S. BULLOUGH, Cancer Research Fellow and honorary lecturer in zoology in the University of Sheffield, has been appointed to the chair of zoology at Birkbeck College, University of London, as from October 1. Dr. Bullough graduated at the University of Leeds in 1935 and after a period of research joined the staff of that University, becoming lecturer in zoology in 1943. During 1944–46 he was lecturer in zoology at McGill University, Montreal. He then returned to Britain as Sorby Fellow of the Royal Society, a post held with that of honorary lecturer in zoology at the University of Sheffield. He was awarded a Senior Cancer Research Fellowship in 1951. Dr. Bullough has a very large body of published research work to his credit. This has included, in a logical sequence, investigations into the reproductive cycles of fish and the seasonal and hormonal factors influencing them; the reproductive and migratory behaviour in the starling and their possible relation to the incidence of foot and mouth disease; and the mammalian œstrous cycle. From a consideration of the mitotic effects of œstrogenic hormones produced by follicular fluid in the mammalian ovary, Dr. Bullough has more lately directed his attention to energy relations of mitosis. Energy must be stored in sufficient available amount before a cell can divide, and once a division begins it will proceed to the end as an 'all or none' reaction. The hormonal control of these rates of energy production, either by stimulation or inhibition, is now the focus of his attention and may well lead to light being thrown on the evolution of hormonal mechanisms in vertebrates as a whole. Dr. Bullough takes to his new duties a rich experience in three universities both in teaching and research, and Birkbeck College may confidently look to him for a continuation of that activity so well cultivated by Prof. A. Graham, whom he succeeds (see *Nature*, July 5, p. 16).

Heriot-Watt College, Edinburgh: Honorary Fellowships

THE Governors of the Heriot-Watt College have conferred the honorary fellowship of the College upon the following, among others: R. Crichton, managing director of Scottish Oils, Ltd., and a governor of the College during 1937–45; G. Mackay, divisional safety engineer, Scottish Division, National Coal Board, and member of the College Mining Consultative Committee; Dr. J. E. Mackenzie, assistant professor of chemistry in the College during 1894–97 and a governor during 1939–51; R. S. Smillie, assistant professor of mechanical engineering in the College during 1919–52; Sir William Wallace, chairman and managing director of Messrs. Brown Brothers and Co., Ltd., Edinburgh, a former governor of the College and a member of its Advisory Committee on Engineering Studies.

University of Leeds

The following gifts, among others, have been announced by the University of Leeds: *Department of Colour Chemistry and Dyeing:* The directors of Johnson Bros. (Dyers), Ltd., of Bootle, a dyeing and cleaning company controlling nine works (among them Pullars of Perth, Eastmans of London and Crockatts of Leeds) are providing an endowment fund of £2,000 to provide two studentships each of £50 a year in the Colour Chemistry and Dyeing Department of the University. This gift is intended to commemorate primarily the services rendered by the late Mr. Oswald Gunnell, recently chairman and managing director of the Company, and also in acknowledgment of help received from the University, at which no less than ten of its chemists and managers have been students in the Dyeing Department. *Department of Botany:* £870 over a period of two years from the Rockefeller Foundation towards the cost of a photographic assistant in plant biophysics. *Department of Leather Industries:* Additional equipment to the value of more than £3,000 from the Turner Tanning Machinery Co., Ltd.; equipment to the value of £500 from Messrs. Barrow, Hepburn and Gale; machine valued at £380 from Messrs. Baker Perkins, Ltd., Peterborough.

Prof. D. Thoday, emeritus professor in the University of Wales, has been appointed visiting professor in the Department of Botany during the session 1952–53; the title and status of reader in biomolecular structure has been conferred upon Dr. K. M. Rudall and Dr. J. MacArthur, Research Fellows in the Department of Biomolecular Structure.

A Recent Sunspot

The largest sunspot for several months came over the sun's east limb on July 9, and for a few days its area exceeded one-thousandth of the sun's hemisphere. This area is not unusual for a spot (spots up to four and even five times this size were observed in 1946, 1947 and 1951), but with the present approach to the minimum of the 11-year sunspot cycle, the appearance of any big spot is noteworthy in itself. A second point of interest was the position of the spot nearly on the sun's equator—1° to 2° south. The circumstances recall the notable equatorial spot of May 1921 which had a mean area for its disk passage of 1,324 millionths of the sun's hemisphere; parts of the spot structure crossed the sun's equator, the mean position being $\frac{1}{2}$° north. This spot was associated with marked disturbance in the earth's geomagnetic field, culminating in a great disturbance lasting from May 13 until May 17—one of the greatest geomagnetic storms ever recorded. However, the recent spot has shown no such parallel of associated geomagnetic or ionospheric disturbance. Only a few minor flares have occurred in Greenwich daylight hours, one of these on July 16 being associated with transient fading on long-distance short-wave radio communication. The joint absence to date (July 19) of intense flares near this sunspot and ionospheric disturbances, both of the solar ultra-violet radiation type and that denoting the effect of solar particles, is significant. By the time this sunspot had reached the central meridian on July 15·1, the area had decreased to about half that when first seen.

Publications in Astronomy from the University of Manchester

The recent growth of activities in astronomy at the University of Manchester has made it desirable to unify the University publications in this field under the general title of "Astronomical Contributions from the University of Manchester", and three series, numbered as follows, will be published. (1) *Annals.* This series is intended to include publications of observational data or other investigations which, on account of their extent, may be unsuitable for printing in current periodicals. The continuous operation of equipment at the Jodrell Bank Experimental Station for measuring meteor, solar and galactic noise has, in particular, yielded a great amount of observational material, and this will be published at irregular intervals as the occasion warrants. In addition, contributions to theoretical astronomy from the University and its Mathematical Laboratory, which because of their size may not be suitable for publication through other channels, will be incorporated from time to time. The first number, dated April 1952, has recently appeared. (2) *Jodrell Bank Reprints.* Papers on radio astronomy which are communicated to, and published by, the learned societies and other scientific journals in the usual way will be reprinted in this series. At present it includes sixty-eight contributions. Some of the back-numbers are available. (3) *Contributions to Theoretical Astrophysics.* This series, which will likewise consist mainly of reprints from scientific periodicals, was initiated recently and so far consists of three numbers (Nos. 1 and 2 being, however, rather scarce). All three series of publications will be distributed to a wide range of observatories, astronomical institutions and individual scientific workers. Requests for additional copies, or suggestions of additional addresses to which the publications should be sent, will be welcome and will be met as long as the supply lasts. Recipients are asked to reciprocate, on an exchange basis, with publications of their own, two copies being required, one to Prof. A. C. B. Lovell, Jodrell Bank Experimental Station, Holmes Chapel, Crewe, Cheshire, and the other to Prof. Zdeněk Kopal, Physical Laboratories, University, Manchester 13.

Protection of Plants in Europe

Both the working parties appointed by the executive committee of the European Plant Protection Organization have now issued their reports (from the Organization at 14 rue Cardinal Mercier, Paris). One party was set up to review the question of the danger to Europe of the introduction of hitherto unreported pests and diseases and to recommend appropriate precautionary measures. The other was asked to examine the quarantine restrictions imposed by governments with regard to certain pests and diseases affecting international trade, and to advise on the general principles on which such restrictions should in future be based. In the first report, twelve pests and diseases are listed affecting, among other crops, fruit trees, roses and potatoes, which would cause serious loss if they became established in Europe. A number of preventive measures such as field inspection, fumigation, post-entry quarantine, seed disinfection and the prohibition of certain packing materials are in general considered adequate to obviate the dangers; but in certain cases an embargo on import might be necessary. Stress is laid on the desirability of limiting permanent governmental restrictions on imports to a minimum, and of utilizing the European Plant Protection Organization as a reporting centre in the event of suspected trouble arising.

The quarantine working party was concerned with four specific plant troubles—Colorado beetle, San José scale, potato root eelworm and potato wart disease. A short account is given of each pest or disease, and the manner by which it spreads. Its control is then discussed in the light of present scientific knowledge so that any legislation imposed may be adequate but not unnecessarily restrictive. For example, distinction is made between the quarantine requirements needed during the active and the hibernating periods of the Colorado beetle. Where fumigation has to be enforced, as in the case of nursery stocks likely to be infected with San José scale, it is suggested that some body such as the European Plant Protection Organization might act as adjudicator on the adequacy of the fumigation arrangements of the exporting country, thereby saving the importer a further fumigation. Other practical recommendations are the discouragement of growing potatoes in nurseries and a plea for the adoption by all countries of a uniform system of soil sampling for eelworm detection. Details of a suitable technique for the latter are given in an appendix. The reports are published in both French and English.

Organization of Nationalized Industries

Nationalized industry forms the theme of a series of research papers published by the Acton Society Trust, and in a recent addition to this series, entitled "Patterns of Organisation" (Nationalized Industry Series No. 9; pp. 32; Claygate: Acton Society Trust, 1951; 2s.), is found a description of the structure of the various nationalized boards together with a critical appraisal of the assumptions underlying their structure. The idea that large organizations are more efficient than small took firm root in the thinking of the inter-war years. Technicians and engineers were absorbed by the idea of being able to plan for bigger units; the trade-union movement was dominated by the idea of relying upon national agreements to prevent inequitable treatment in any single area; and when the Second World War came, administrators learned successfully how to operate nation-wide controls. The present patterns of organization have been determined by the coincidence in time of these trends; and the Acton Society Trust pamphlet points out that it has been too readily assumed that the limiting factor is the capacity of management to manage, to the neglect of much evidence that the limiting factor resides in the capacity and needs of the workman. The human factors—desire for status, resistance to change, fear of the future—impede the introduction of changes which the new regime was intended to bring about. Basic units in each industry should be small enough to preserve loyalties and personal contacts between managements and employees and between the industry and the public. It is also argued that the co-ordination of these units can be achieved by some much looser system of organization than that at present operating.

Shirley Institute: Report for 1950

The "Shirley Institute Year Book, 1951" (pp. 125; Manchester: British Cotton Industry Research Association, 1951) includes, besides the annual report for 1950, concise accounts of its present organization and services to members with plans of the proposed extensions and the existing offices, laboratories and workrooms, and a chronology of the Institute's historical background and growth. The annual report includes an account of the ceremony on June 14, 1950, of the laying of a foundation stone for the new building scheme, with reports of the speeches made then and at the annual general meeting of the Association on November 9, 1950. Tributes are paid in the report to the services of Dr. J. C. Withers, who retired at the end of September 1950 after thirty years of service as head of the Information Bureau, chief librarian and editor of the "Summary of Current Literature", and to L. H. C. Tippett, head of the Mechanical Processing Division, who was awarded the Warner Medal of the Textile Institute on June 8. The major change in internal administration during the year was the appointment of J. H. Black as head of a new Information Department to co-ordinate all the information services of the Institute, including the library, abstracting, technical inquiries and publications, and the illustration office. Among research results stress is laid on the successful industrial application of the Shirley accelerated drying device and the introduction of the Shirley automatic size box, a revolutionary method of regulating the percentage of size added to the warp before weaving. The Shirley electrostatic eliminator, designed for the rapid removal of static electricity in high-speed processes, seems likely to be of value in other industries. Besides a list of members on January 1, 1951, appendixes to the report give details of the Council, committees of Council, publications of the Institute in 1950, and periodicals taken by and books added to the Library.

Italian Society of Geophysics and Meteorology

The Italian Meteorological Society, founded in 1881, unfortunately had to discontinue its activities during the Second World War. Prof. M. Bossolasco, Geophysical Institute, University of Genoa, who has been very active of recent years in the organization of international geophysical symposia in Italy, now writes, as secretary, to announce the foundation during May of the Italian Society of Geophysics and Meteorology. The Society's interests are planned to cover a very wide scope: they will include meteorology with climatology and bioclimatology, terrestrial magnetism, atmospheric and telluric electricity and radioactivity, seismology, volcanology, oceanography, hydrology, geodesy and geophysical prospecting and their applications. It is planned to begin publication of a Bulletin in the autumn. Membership, which is stated to be already some 120, is open to foreigners as well as Italians, and applications are invited; the annual subscription, which covers supply of the Society's publications, is only 500 lire. British geophysicists and meteorologists will wish the new Society every success.

Plastics Industry Education Fund

The trustees of the Plastics Industry Education Fund, the chairman of which is Mr. P. C. Allen, have recently announced that the total sum they have made available or authorized for expenditure during 1952 is £4,700. Some of the details of this money are as follows. £1,000 is to be made available during the year for the award of ten training grants for students and £100 for travelling and educational expenses for apprentices attending recognized technical colleges.

It has been decided to revise and re-print four of the series of technical monographs originally published by the Plastics Institute, and £1,000 has been allocated for this purpose. £200 has been allocated for the purchase of text-books for the libraries of the local sections of the Institute, with a further special donation of £200 to establish a library for the newly formed South Wales and Monmouth Section. It has been agreed to allot £1,250 for the purchase of capital equipment for technical colleges during 1952, and the trustees have asked the Plastics Institute to make specific recommendations concerning the equipment to be purchased and the colleges to benefit.

International Congress of Psychology

The International Congress of Psychology will hold its next meeting, in 1954, in Montreal, instead of in New York as previously planned. The American Psychological Association and the Canadian Psychological Association will be joint hosts for the meeting. In making this announcement, the American Psychological Association gives as the main reason "the delays and embarrassments which foreign scientists experience in attempting to obtain even temporary admission to this country". The Internal Security (McCarran) Law is considered to be responsible, and, by its restrictive action, to be damaging the exchange of ideas between the United States and the rest of the world. Some two thousand psychologists are expected to attend the congress in Montreal.

Instruments and Measurements: Conference in Stockholm

The Royal Swedish Academy of Engineering Sciences (I.V.A.) and the Association of Technical Physicists (T.F.F.) are arranging an "Instruments and Measurements Conference 1952" to be held in Stockholm during September 22–25. The Conference will be organized into the following main groups: methods of measurement in physical chemistry; methods of measurement and control in industry; mechanical methods of measurement and metrology; methods of measurement in nuclear physics and radioactivity; and miscellaneous methods of measurement. Symposia will be arranged in the first four groups. The official languages of the Conference will be English, German and French. A preliminary programme, with a list of papers, is now ready. All communications regarding the Conference should be addressed to Yngve Axner, Kungl. Tekniska Högskolan, Stockholm 70. An exhibition of instruments and laboratory equipment will be held in the Exhibition Halls of the St. Eriks Fair during September 23–30, to which members of the Conference will be admitted free of charge. Further information on the exhibition can be obtained from St. Eriks-Mässan, Lidingövägen 10, Stockholm 26.

The Night Sky in August

Full moon occurs on Aug. 5d. 19h. 40m., u.t., and new moon on Aug. 20d. 15h. 20m. The following conjunctions with the moon take place: Aug. 4d. 18h., Mercury 6·4° S.; Aug. 12d. 17h., Jupiter 7° S.; Aug. 19d. 12h., Mercury 4° S.; Aug. 22d. 06h., Venus 4° N.; Aug. 24d. 15h., Saturn 7° N.; Aug. 28d. 05h., Mars 3° N. Mercury is in inferior conjunction on Aug. 12 and cannot be observed during the first part of the month; towards the end of the month it is a morning star, rising at 3h. 30m. on Aug. 31, when its stellar magnitude is 0. Venus, an evening star, rises at 20h. 15m., 19h. 55m., and 19h. 25m. at the beginning, middle and end of the month, respectively, stellar magnitude − 3·3. Mars is an evening star, setting at 22h. 30m., 21h. 55m. and 21h. 15m. on August 1, 15 and 31, respectively, its stellar magnitude varying from 0 to 0·3 during this period. It is close to α Libræ early in the month and moves eastward until it is a little south of β Scorpii at the end of the month. Jupiter rises at 23h., 22h. 10m. and 21h. 10m. on Aug. 1, 15 and 31, respectively, stellar magnitude about − 2. The planet is nearly 3° south of δ Arietis during most of August. Saturn is an evening star, setting at 21h. 50m., 21h., 19h. 55m. at the beginning, middle and end of the month, respectively, stellar magnitude 1·1. It moves from a position close to γ Virginis to north of θ Virginis during August. The Perseid meteors will be active during the month, the maximum of the shower occurring about August 10–12.

There will be a partial eclipse of the moon on Aug. 5, partly visible at Greenwich. The circumstances of the eclipse are as follows:

Moon enters penumbra	Aug.	5d.	17h.	26·6m.
Moon enters umbra		5	18	33·4
Middle of the eclipse		5	19	47·4
Moon leaves umbra		5	21	01·4
Moon leaves penumbra		5	22	08·2

The magnitude of eclipse is 0·538, the moon's diameter being 1·0. An annular eclipse of the sun on August 20 is invisible at Greenwich. It will be visible over portions of South America.

Announcements

The following appointments have been announced by the University of Sheffield: F. T. Williams, lecturer in the Postgraduate School of Mining; B. R. Pursall, lecturer in the Department of Mining; P. H. Price (at present research assistant to the professor of fuel technology) to be lecturer in fuel technology; R. G. Siddall, research assistant to the professor of fuel technology; E. H. Gillespie, honorary lecturer in bacteriology. Dr. B. Donovan, lecturer in physics, has resigned on appointment as senior lecturer in physics at the Northern Polytechnic, London.

The Research Fund of the Chemical Society provides grants for the assistance of research in all branches of chemistry. About £700 per annum is available for this purpose, the income being derived from a donation of the Worshipful Company of Goldsmiths, from the Perkin Memorial Fund, and from other sources. Applications for grants should be submitted to the General Secretary, The Chemical Society, Burlington House, Piccadilly, London, W.1, on the appropriate form not later than November 15, 1952.

The American Embassy and the United States Educational Commission in the United Kingdom announce a programme of grants to assist senior British scholars to lecture or carry out research in the universities of the United States. The grants will be paid in dollars, and they will be tenable for the academic year 1953–54; the monthly stipend will not be more than 270 dollars. Applicants must be citizens of the United Kingdom or Colonies, and should have a plan for research which can be effectively carried out in the time they propose to spend in the United States; they must arrange their own affiliation with a university in the United States. Application forms, to be returned before November 15, can be obtained from the Assistant Cultural Relations Officer, Room 302, 41 Grosvenor Square, London, W.1.

ORIGIN OF THE DEFORMATION TEXTURES OF TITANIUM

By D. N. WILLIAMS and Prof. D. S. EPPELSHEIMER
Missouri School of Mines and Metallurgy, Rolla, Missouri

BY proper choice of assumptions, it has been possible to develop a satisfactory theoretical explanation of the tension, compression, and cold-rolled textures of titanium using the graphical method of texture analysis recently reported by Calnan and Clews[1].

The observed textures of titanium can be summarized briefly as follows: *tension*, strong [10$\bar{1}$0][2]; *compression*, [0001] rotated 30° from the compression axis at low reduction. Angle of rotation decreases with increased reduction. Some evidence indicates that <10$\bar{1}$0> is the preferred axis of rotation[3]; *cold rolled*, (0001) [10$\bar{1}$0] rotated 30° or more toward the transverse direction[4]. It is apparent from these results that some mode of deformation previously unreported in hexagonal metals is occurring in titanium.

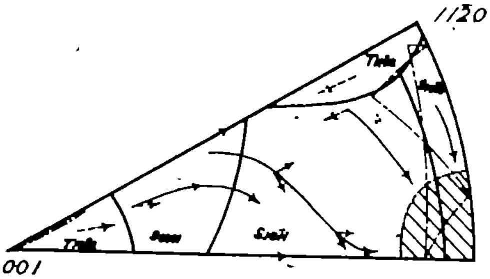

Fig. 1. Theoretical tension texture of titanium

Rosi, Dube and Alexander[5] report that at low reductions titanium exhibits {1010} <11$\bar{2}$0> and {10$\bar{1}$1} <11$\bar{2}$0> slip, and {11$\bar{2}$2}, {11$\bar{2}$1} and {10$\bar{1}$2} twinning. Although they found no evidence of {0001} <11$\bar{2}$0> slip, examination of the deformation textures shows that it must be present, at least at higher reductions.

These modes of deformation were examined separately and then combined to give the observed deformation textures. A satisfactory theoretical texture was developed when the critical shear stresses for slip (C_s) and twinning (C_t) were related as follows: C_s(0001) = 1·1 C_s(10$\bar{1}$1) = 1·02 C_s(10$\bar{1}$0) = C_t(1122) = C_t(10$\bar{1}$2). Since {11$\bar{2}$2} and {11$\bar{2}$1} twinning have the same general effect, only {11$\bar{2}$2} twinning was considered.

The areas within the unit stereographic triangle in which each of the above modes of deformation is favoured are shown in Figs. 1 and 2 for tension and compression respectively. Twinning reorientations are shown by dashed arrows, and slip rotation tendencies by full arrows. The final texture resulting is shown by the shaded areas.

The cold-rolled texture may be approximated by assuming tension in the rolling direction and compression along the rolling plane normal. In Fig. 3 the 0001 pole figure which would result is shown.

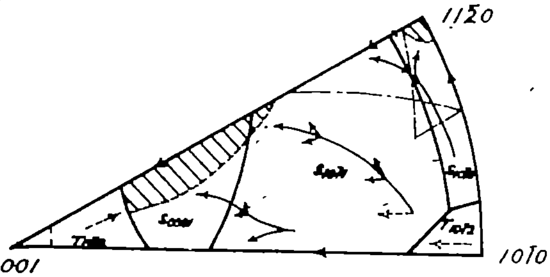

Fig. 2. Theoretical compression texture of titanium

Tension in the rolling direction causes those 0001 poles within 29° of the rolling direction to twin on the {10$\bar{1}$2} planes to a region near the transverse direction. {11$\bar{2}$2} twinning in compression removes 0001 poles within 30° of the rolling plane normal to a new position along the circumference of the pole figure. Twinning reorientations are shown by dashed arrows.

Slip can be assumed to result from combination of compression and tension tendencies. Compression rotates the 0001 poles toward the normal to the rolling plane. Tension rotates the 10$\bar{1}$0 poles into the rolling direction and thus rotates the 0001 poles toward the transverse axis. The tension and compression rotations are shown by arrows marked *T* and *C* in Fig. 3. The resultant rotation is marked *R*.

As the amount of cold-rolled reduction increases, a point is soon reached beyond which the principal movement is slip rotation by compression toward the normal to the rolling plane along the transverse axis, followed by twinning at an angle of 30° from the

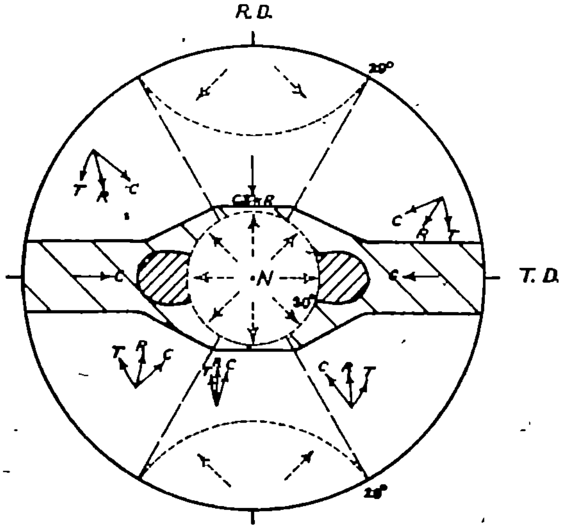

Fig. 3. Theoretical 0001 pole figure of cold-rolled titanium

normal to the rolling plane back toward the transverse direction. The slip rotations and twinning reorientations will occur by rotation about a fixed set of 10$\bar{1}$0 poles in the rolling direction. The resulting 0001 pole figure is shown by shading in Fig. 3.

Complete details of the analysis of the various modes of slip and twinning, along with experimentally determined textures using Geiger-counter techniques, will be published elsewhere.

The work described above was carried out under a research fellowship supported by the Titanium Alloy Manufacturing Division of the National Lead Company.

A NEW APPROACH TO THE PROBLEMS OF THE SPREAD OF APHIDS AND TO INSECT TRAPPING

By DR. C. G. JOHNSON

Rothamsted Experimental Station, Harpenden

IN recent work with *Aphis fabæ*[1], trapped while flying from infested bean crops, the usual statistical procedures failed to distinguish fluctuations in numbers due to flight behaviour from those due to population changes. This makes it necessary to reconsider current views on the spread of aphids as well as the analysis of trap data in entomological research.

Current Views and Recent Work on Aphid Migration

Resting winged aphids when exposed to winds greater than 1·5–2·0 m.p.h. will not take flight[2-5]. It has therefore been inferred that relatively little migration occurs in windy weather[3,4,6], although shelter may allow some to take place from within crops[6-8]. This idea seemed to be supported by the results of trapping in the field[9,10] and also by the fact that high aerial concentrations are commonly seen only in calm weather and because only then are single plants colonized[11]. Moreover, take-off, colonization and numbers in the air have all been considered in relation to the weather of the occasion, so tacitly over-emphasizing the role of flight behaviour in migration changes. Observations on the actual numbers of aphids in the air over continuous, consecutive, short periods, adequately associated with meteorological data, have hitherto been lacking. Such observations have now been made with suction traps[1,12], and so far from indicating that most migration occurs in calm weather, the opposite appears to be the case.

Correlations between wind-speed and the numbers of *A. fabæ* and other species[1,12] in the air, though sometimes statistically significant, are not strong. Rapid periodic changes in the number of winged aphids on the crop mask the effect of weather-induced changes in the percentage which fly. This factor, hitherto insufficiently appreciated, is partly due to accumulation of alatæ in the interval between moulting and flying, and partly to their depletion on the crop by flight. A 100 per cent take-off from 100 aphids on one day produces a smaller flight than a 50 per cent take-up from 300 on the next; and successive increases in percentage which fly could be accompanied by successively smaller catches as the population diminishes. In fact, it is impracticable to assess degrees of take-off from aerial numbers alone, or vice versa. Even where aerial numbers and wind-speed were negatively correlated, the scatter showed that considerable flights occurred in windy as well as in calm weather. Moreover, mass migration is possible without any local accumulation in the air at low levels; for example, 995 *A. fabæ* were caught in 20,000 cu. ft. at crop-level (a very high density) on July 6, 1949, but the aphids flew upwards from a sheltered situation into a windy one.

Other evidence that has come from our continuous trapping is that only 23 per cent of all the *A. fabæ* trapped over the whole migration period of five to six weeks (and 25 per cent of all other aphid species) were caught during hours when the mean wind-speed was less than 3 m.p.h. Since the trap measures aerial density, catch × wind-speed × hours indicates the number of insects passing a vertical front of constant area at trap-level: by this calculation only 7 per cent of all the *A. fabæ* (and of other aphid species 9 per cent) passed at mean wind-speeds less than 3 m.p.h. Thus nearly all the aphids flying were being dispersed during relatively high wind velocities with little or no voluntary control of direction.

This result is largely due to the few calm hours which occur in south-eastern England during the periods of the day when aphids fly; in July 1949 only 19 per cent had mean wind-speeds less than 3 m.p.h.

Analysis of Trap Data in Entomology

The number of insects in the air is a compound effect of population-level and degree of flight 'activity'. The separation of these two factors in trap data has usually been attempted by statistical procedures, on the assumption that relatively long-term changes are largely due to population fluctuations, short-term ones depending more on activity[13,14]. Thus fluctuations in the running means of catches are assumed to reflect chiefly population change, short-term deviations from the running mean chiefly flight activity. Similarly, differences between the logarithms of catch for successive days or nights have been taken to indicate activity; and differences between two days at wider intervals to reflect population change[14]. This method may work with relatively stable populations when insects return to the locality after flight or, if they migrate, they are replaced by an equivalent number from elsewhere. But the method fails with aphids[1], and no doubt with other insects where rapid, large population changes contribute more to changing numbers than do variations in flight behaviour. It appears, therefore, that this method of analysis cannot be used indiscriminately without regard for the biology of the insects concerned; for deviations from a running mean or differences between the logarithms of successive catches will reflect either population, immigration or other behaviour changes, according to which has the greater effect on aerial numbers. Thus Muller and Unger's results[4,5] for *A. fabæ* obtained by the use of deviation analyses must be treated with reserve, for they may reflect moulting-rate more than flight activity.

I have found that the greatest numbers of aphids migrated in windy weather; therefore, a lack of colonization may be due, not to absence of migration, as previously thought, but to unsuitable conditions for alighting. The significant epidemiological factors may not be take-off changes so much as population-levels, alighting behaviour, and the kinds of crops and situations which affect it.

Alighting requires calmness: therefore, single plants[11] or crops affording little shelter may possibly be colonized only in the relatively infrequent calm periods. This type of aphid distribution might be associated more with short flights favouring the transmission of viruses with a short life in the aphid. On the other hand, crops providing plenty of shelter among stems, or on the lee side, may be colonized continuously by longer-range flights of wind-borne aphids, and this type of dispersal may be associated more with persistent viruses.

Traps are of undoubted value in measuring aerial populations. But it must be emphasized that they are not always suitable instruments, when used by themselves, for the analysis of population and activity factors. [April 18.

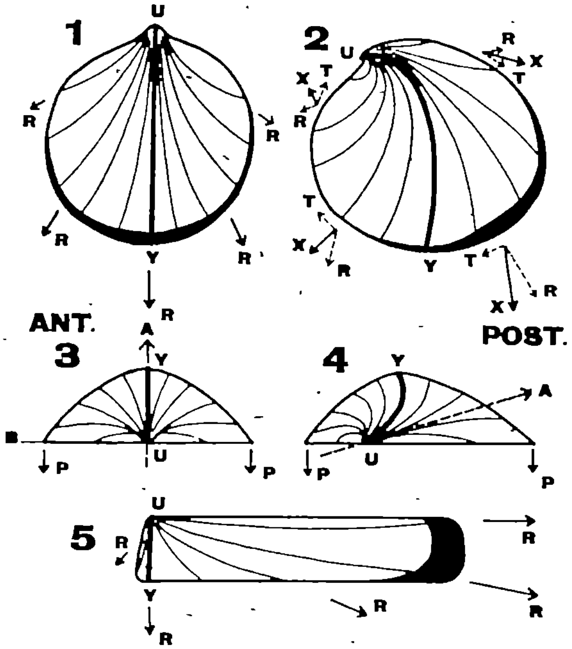
SHELL-FORM IN THE LAMELLIBRANCHIA

By G. OWEN

Zoology Department, University of Glasgow

In the Lamellibranchia, marginal increase of the shell valves results from the activity of the mantle edge which is thus responsible for the form of the shell. The direction of growth at any region of the mantle edge may be conveniently resolved into a number of components. In the primitive bivalve, the form of both valves was probably the resultant of: (*a*) a radial component radiating from the cardinal region of the hinge and acting in the plane of the generating curve (represented by the valve margin); (*b*) a transverse component acting at right angles to the plane of the generating curve. Certainly the form of the shell valves in many modern lamellibranchs, for example, *Glycymeris* (Fig. 1) and *Tellina*, is the resultant of radial (*R*) and transverse components (Fig. 3, *P*). In some genera, for example, *Pecten* and *Gryphaea*, growth of only one of the valves is the resultant of these two components; growth of the other, flat valve is the result of the radial component only.

The magnitudes of the radial and transverse components increase from either end of the ligament around the margins of the mantle and shell edge (Fig. 1). Thus, there is a region of the mantle edge ventrally where the effect of the transverse component is greatest (*Y*). In those lamellibranchs in which the generating curve is in one plane (that is, unlike members of the Myidae and Pholadidae), it is proposed to describe this region as the 'normal zone' of the mantle edge. Since the effect of the transverse component is greatest at this region, the normal zone secretes that sector of the shell which exhibits the greatest concavity and in this sense is the *Gewölbescheitelbahn* defined by Haas[1]. It is proposed to designate a line (*UY*) drawn along the centre of this sector of the shell as the 'normal axis' of the lamellibranch mantle and shell. The normal axis can thus be considered with reference to three points: the umbo, the normal zone of the mantle edge and the point at which the greatest transverse diameter of the shell intersects the surface of the valves.



Figs. 1, *Glycymeris*; 2, *Venus* type bivalve; 3 and 4, the right valves of 1 and 2 viewed from the umbonal region, that is, dorsally; 5, *Ensis*.

AU, directive plane; *P*, transverse component; *R*, radial component; *T*, tangential component; *U*, umbo; *UY*, normal axis; *Y*, normal zone; *X*, the direction of growth in Fig. 2. In Figs. 1, 2 and 5 the transverse component acting perpendicular to the plane of the page is not shown. The thickened regions at the valve margins indicate greatest marginal increment

In those bivalves in which the form of the shell valves is the resultant of these radial and transverse components alone, for example, *Glycymeris* (Fig. 1), *Tellina*, *Anodonta* and *Ensis* (Fig. 5), the normal axis (*UY*) is in one plane; that is, it is a plano-spiral. Each of the valves would, if a complete whorl were produced, describe a plano-spiral about the umbo. Enlargement of the generating curve with growth results in the growth curves anterior and posterior to the normal axis being increasingly displaced from the normal plane, so that, unlike the normal axis (*UY*, Figs. 1 and 5), they are turbinate spirals. The form of the shell valves in many lamellibranchs, however, is affected by an additional component acting tangentially to, and in the plane of, the generating curve (Fig. 2, *T*). In genera such as *Cardium*, *Venus* or *Mytilus*, as a result of this tangential component, the normal axis (*UY*) is no longer a plano-spiral but a turbinate spiral. In this case, each valve would, if a complete whorl were produced, describe a turbinate spiral about the umbo.

Growth of the shell valves in *Glycymeris* (Fig. 1) is not affected by a tangential component. The normal zone (*Y*) is mid-ventral and coincides with the region of greatest marginal increment. Moreover, both marginal increase and the effect of the transverse component decrease symmetrically around both sides of the mantle and shell edge. Each valve is therefore symmetrical about the normal axis. The normal zone, however, need not coincide with the region of greatest marginal increase. Thus, in *Gari tellinella*, the generating curve is an ellipse which is roughly symmetrical about the normal axis. There are two regions of maximum marginal increase symmetrically disposed at either end of the ventral margin. The effect of the transverse component remains, however, greatest mid-ventrally. But in genera such as *Anodonta* or *Ensis* (Fig. 5), the generating curve is asymmetrical about the normal axis (*UY*). Maximum marginal increase takes place posteriorly while the normal zone (*Y*) remains ventral to the umbo. The normal axis is in one plane and, as in the symmetrical shells of *Glycymeris* and *Gari*, each valve would, if a complete whorl were produced, describe a plano-spiral about the umbo.

The form of the shell should, therefore, be considered with reference to: (*a*) the form of the spiral (namely, plano- or turbinate) of the normal axis; (*b*) the spiral angle of the normal axis (giving a measure of the concavity of each valve); (*c*) the outline of the generating curve.

Lison[2] claims that the form of the lamellibranch shell is dependent on: (*a*) the angle of the directive spiral; (*b*) the angle of incidence, that is, the angle between the directive plane and the plane of the generating curve; (*c*) the outline of the generating curve. Much depends on Lison's concept of the 'directive plane' of the lamellibranch shell. This is defined by him as follows: "Chez les lamellibranchs existe toujours un plan et un seul, dans lequel s'inscrivent sur toute leur longueur une ou des côtes représentant des courbes planes. Ce plan, qui passe nécessairement par l'umbo, sera appelé le plan directeur de la coquille". According to Lison, this directive plane may be perpendicular to the plane of the generating curve (for example, *Pecten*), or it may be, as in the majority of lamellibranchs, more or less inclined to the plane of the generating curve.

In those genera (*Glycymeris*, *Gari*, *Anodonta* and *Ensis*) in which the 'angle of incidence' is 90° (Fig. 3, *AUB*), the plane of what is here described as the normal axis (*UY*) is identical with this directive plane (*AU*). These, however, are all lamellibranchs in which there is ***no tangential component*** affecting the form of the shell. In *Corbis fimbriata*, quoted by Lison as possessing the directive plane inclined to the plane of the generating curve, there is a small tangential component (Fig. 2, *T*). As shown in Fig. 4, the normal axis (*UY*) is no longer in one plane, and the turbinate spiral ribs posterior to the normal axis are 'deflected' anteriorly as a result of the tangential component. It follows that one of these ribs will come to lie effectively in one plane (Fig. 4, *AU*). As shown in the diagrams, change in the position of the directive plane is a result of the tangential component and will be related to the magnitude of this component. Moreover, in members of the Chamidæ and Glossidæ (that is, *Isocardia*) the magnitude of the tangential component is such that *all* growth curves of the mantle and shell are turbinate spirals; there cannot, therefore, be any directive plane as defined by Lison.

It is hoped to discuss elsewhere the effect of the tangential component on the ligament and hinge teeth. It should be noted, however, that in the majority of lamellibranchs in which the form of the mantle and shell is affected by a tangential component the anterior region of the ligament is progressively split as growth proceeds. MOLYBDENUM IN RELATION TO CROPPING AND LIVESTOCK PROBLEMS UNDER IRISH CONDITIONS

By Dr. T. WALSH and M. NEENAN
(Soil Laboratory)
and Dr. L. B. O'MOORE
(Veterinary Research Laboratory)
Department of Agriculture, Ireland

IT has been shown[1-3] that molybdenum, although an essential element in plant nutrition, can, when present even in moderate excess in herbage, cause nutritional disorders in livestock. Investigations which we have on hand on the importance of this element under Irish conditions have indicated that it may be of considerable importance from both the deficiency and toxic aspects. Some of the more important findings of this research are recorded here.

Deficiency aspects. When a sandy loam soil of pH 5·3 and low calcium status was used in a pot experiment with *Trifolium subterraneum* as an indicator crop, a striking response was obtained from the application of a small quantity of molybdenum, this response being specially evident in the presence of mono-calcic phosphate. A field experiment with swedes on a soil of similar type also showed a response to applications of molybdenum. This soil also gave a highly significant response to the application of lime, and results now available from the analysis of soil and herbage point to this response as being due in part at least to an increase in the availability of molybdenum in the soil following liming.

When investigating a case of infertility in an organic soil (loss on ignition 95 per cent, pH 5·5, available calcium 2,500 p.p.m. and moderately well supplied with major elements), it was found in pot experiments using *S*.100 white clover as an indicator crop that, while the application of a full supplement of nitrogen, phosphate and potassium caused little if any improvement in growth, a striking response was obtained when molybdenum was added to this dressing. A similar response was obtained from the full supplement plus chalk while, on the other hand, the addition of copper sulphate to the full supplement caused a definite depression in growth. Analysis of the herbage showed that the plants receiving the nitrogen–phosphate–potassium supplement contained 2·5 p.p.m. of molybdenum. Those receiving chalk in addition contained a similar level, whereas those receiving copper sulphate contained less than 0·5 p.p.m. of molybdenum. Plants receiving nitrogen–phosphate–potassium plus molybdenum (5 p.p.m. of soil) contained 24 p.p.m., rising to 38 p.p.m. where 20 p.p.m. of molybdenum was applied to the soil. This instance of molybdenum deficiency in organic soil appears to be unusual, as hitherto such conditions have been usually associated with toxicity of this element[1].

Excess. Instances of a syndrome occurring in cattle associated with unthriftiness, stunted growth in young animals and rough, staring, depigmented coats have been investigated in a number of areas. The coats of red-coloured animals sometimes assume a faded yellow appearance, while although scouring is not a constant feature it has been observed in a few cases. Symptoms are generally similar to those described by other workers[2,4] as being due to a conditioned copper deficiency. Copper dosage is specific as a control. While analysis of herbage samples where affected cattle are depastured have shown normal copper values, that is, greater than 7 p.p.m. (dry matter), the molybdenum content ranged from 5 to 20 p.p.m. On the basis of data quoted elsewhere[3] in connexion with a similar condition in livestock, the above figures are well within the range which represents a moderate excess, the accepted normal for herbage being in the range 1–3 p.p.m. We have also verified the latter figures for normal pasture. It seems reasonable to conclude that the level of molybdenum reported is at least partly responsible for the occurrence of this condition in livestock. While in some of the animals examined the blood copper values tended to be low, that is, of the order of 0·3 mgm./litre, this was by no means a constant finding. Hæmoglobin-levels were normal, and hæmatological studies presented no evidence of anæmia. In view of other findings[5] where an association has been established between defects in bone building in cattle showing symptoms of copper-deficiency and the effects of molybdenum on the utilization of copper and indirectly of phosphorus, it is of considerable interest that we have found the condition reported to be invariably associated with herbage of high calcium content and often of wide calcium to phosphorus ratios, while in several instances blood determinations have shown that deficiencies of both copper and phosphorus co-existed in the same animal.

While this condition occurs frequently on organic soils very similar to those described[3] as being associated with 'peat scours' and other nutritional troubles in livestock, in our investigations it has in addition been found to occur on what are otherwise fertile loams of limestone derivation and typical of important and widely distributed soil series. It may be of further interest that, where the worst excesses have been reported on these mineral soils, the phosphate-level of the latter has been satisfactory. This corresponds with the experience elsewhere[6], as phosphate has been shown to increase molybdenum uptake and also agrees with our pot-culture findings reported above. In two instances also, basic slag used as a fertilizer accentuated the trouble, this being attributable not only to the phosphorus effect but also to the fact that basic slag contains appreciable quantities of molybdenum.

The total molybdenum content of the soils examined, with one exception so far, and representing both the deficiency and excess conditions, was normal, with a range of 0·42–3·50 p.p.m. In one soil a level of 20 p.p.m. has been found. It was found that where response to molybdenum was obtained, the values were less than 0·12 p.p.m. available molybdenum, the latter being determined by the oxalate method, whereas in the soils where the herbage contained excess quantities the soil values were very considerably higher, varying from 0·30 to 0·57 p.p.m. of available molybdenum. Where deficiencies have been identified, the *p*H of the soils varied from 4·9 to 5·5; that in soils associated with this nutritional disorder and excess molybdenum in the herbage have ranged from *p*H 6·5 to 7·8. This corresponds with other observations[7,8] which show that the availability of molybdenum is greatest within the latter *p*H range. It may be of further interest also that, when a fertile soil which contained a total of 0·86 p.p.m. of molybdenum and had a *p*H of 7·8 was used in a pot experiment with *T. subterraneum*, the latter contained 14 p.p.m. of molybdenum, whereas an acid soil of higher total molybdenum content (3·5 p.p.m.) gave a value of 0·5 p.p.m.

It is apparent that this work raises many interesting points in connexion with the treatment of pasture. Investigations are proceeding and will be reported more fully elsewhere. [March 3.

PRINCIPLES AND APPLICATIONS OF ION EXCHANGE

A SYMPOSIUM on the "Principles and Applications of Ion Exchange" was held at the University of Manchester on March 27 under the joint sponsorship of the Royal Institute of Chemistry, the Chemical Society, the Society of Chemical Industry and the Institute of Petroleum. In addition to the papers contributed, an exhibition of apparatus, with demonstrations, was on view.

In the morning session, on theoretical aspects (chairman, Prof. C. W. Davies, University College of Wales, Aberystwyth), Dr. K. W. Pepper (Chemical Research Laboratories, Teddington) gave the first paper, on "Chemical Structure and Physical Characteristics of Ion-Exchange Materials". He illustrated the concept of ion-exchange resins as insoluble acids and bases by reference to certain aspects of their reactions—for example, equivalence of exchange, reversibility and accessibility of functional groups as exchange sites. After describing the preparation and chemical structure of a number of resins in some detail, particularly the most chemically stable cross-linked polystyrene type, Dr. Pepper gave an account of the characteristic behaviour of the principal types of cation and anion exchangers and indicated the influence of the degree of cross-linking of the polymeric framework on swelling, rates of exchange and equilibria.

In his paper on "Physical Chemistry of Ion Exchange Equilibria and Kinetics", Dr. J. A. Kitchener (Imperial College of Science and Tech nology, London) pointed out that equilibria and kinetics are relevant to practical use of resins since they govern selectivity and speed of operation. Three principal theoretical treatments, complementary rather than contradictory, have been tried involving, respectively, the law of mass action, Donnan membrane equilibrium, and ion exchange as an interaction between individual ions and charged sites. It has become clear that an adequate treatment must make allowance for the work of swelling and particularly for ionic interactions in the resin phase, a matter presenting considerable theoretical difficulty. The kinetics of ion exchange can be broadly explained by a diffusion mechanism; but a detailed quantitative theory in terms of resin structure has not yet been developed.

Dr. E. Glueckauf (Atomic Energy Research Establishment, Harwell) then discussed "Factors Affecting the Operation of Exchange Columns", indicating that while some separations depend on the separating power of the resin, others depend on a complexing produced in the aqueous phase. Resins with higher cross-linking are more suitable for the first type, but a lower cross-linking is better for the second. He referred to the factors, in column operation, which affect the sharpness of chromatographic bands, and distinguished between three different modes of column operation: removal of impurities (as in water softening), displacement chromatography, and development chromatography. The first two lead to fast separations and are preferable for industrial applications, but there is no complete separation into isolated bands. This only happens with the third mode, which lends itself to analytical uses. Dr. Glueckauf mentioned a recent innovation of 'gradient development' which employs an eluting solution of constantly increasing strength.

In the discussion, Dr. Kitchener, replying to Mr. J. A. Dukes, stated that he had referred to the hydrated ion when speaking of the effect of ionic size on exchange kinetics. Mr. D. K. Hale commented upon the large variations in the mass law product which can accompany variations in cationic composition of the resin and quoted supporting results of the cation pair $N(C_2H_5)_4^+$ and H^+, for a sulphonated cross-linked polystyrene. Treatment of the resin with an excess of $N(C_2H_5)_4OH$ causes an irreversible structure-change consistent with a decrease in cross-linking. Mr. Hale also mentioned difficulties which may be encountered when performing chromatographic separations with resins of low cross-linking, and stated that surface sulphonated polystyrene resins may help in difficult separations. Dr. Glueckauf reported experiments by Dr. Barker demonstrating the charged double layer, most pronounced in very dilute solutions, surrounding resin particles. Due to electrostatic repulsion, friction between resin particles is reduced, as shown by the angle of repose of a tilted bed. The effect is not shown by silver resinates.

Dr. D. D. Pratt (director, Chemical Research Laboratories, Teddington) opened the afternoon session on practical applications. In the first paper, on "Practical Applications of Ion Exchange in Water Treatment", Dr. E. I. Akeroyd (Permutit Co., Ltd.) reviewed the various types of ion-exchange materials, their applications in a number of water treatments, and plant and control instruments. He described the deionization of water and discussed the classical two-bed system, the more recent mixed-bed method, and the newer anion-exchange resins which can remove silica and other very weak acids. Dr. J. Hope (Charles Lennig and Co., Ltd.), speaking on "Other Applications", surveyed the uses of ion-exchange materials in the purification of formaldehyde and glycerine, in processing beet sugar, and in the pharmaceutical industry (for example, manufacture of streptomycin). He also described interesting therapeutic applications, such as the treatment of peptic ulcers, heart disease, cirrhosis of the liver, and the estimation of gastric acidity.

In the last paper of the session, on "Laboratory Applications", Dr. J. E. Duncan (Harwell) dealt with three general uses of ion exchange. The first is as adsorbates—for example, in chromatographic separation of ions by direct elution with acids and alkalis, elution with complexing agents, separation of non-electrolytes from electrolytes and separation of trace amounts; such procedures are of interest in both preparative and analytical chemistry and, in the latter case, ion-exchange is easily adapted by a radio-activation procedure and by the isotope dilution method. The other two uses are as laboratory reagents for titration, buffering and catalysis, and as a physico-chemical technique for the determination of ionic charge, ionic concentration, ionic size and molecular size (using dry ion exchangers as molecular sieves). In the last four applications mentioned, a detailed knowledge of the physico-chemical behaviour of the ion exchange is usually necessary.

During the discussion, Dr. B. A. J. Lister briefly described a study of the ionic size, charge and degree of formation of cation complexes in the case of zirconium, and in answer to Mr. E. Foley stated that the hydrolysis scheme for zirconium is not reversible and that hafnium may accompany zirconium in complexes. Dr. Duncan, in reply to Mr. Stevenson, quoted work by Kressman and Kitchener and others on the use of ion exchangers to determine the size of dye molecules. Mr. N. A. Hurt put a question on the removal of ammonia by cation exchangers and its effect on their capacity in water treatment. Dr. Akeroyd stated that 95 per cent of the ammonia could be removed and demonstrated the point of 'break-through' diagrammatically. A question by Dr. E. M. Meade on Sn^{2+}, Cr^{2+} or Ti^{3+} resins as reductors or basic resins in the CrO_4^{2-} or MnO_4^{-} form for oxidations was deferred to the evening session, in view of the comments to be made by Dr. Fairbrother. Dr. Pepper summarized applications of ion exchange in organic chemistry.

Further developments of ion-exchange materials were discussed at the evening session (chairman, Dr. F. Fairbrother, University of Manchester). Dr. R. E. Kressman (Permutit Co., Ltd.), in his paper on "Ion-Exchange Resin Membranes", described continuous sheets and rods made from both cation and anion exchangers, normally produced in granular form, and, in particular, described electrodes made from a sulphonated phenol type of resin. As expected on theoretical grounds, when these membranes separate two pure solutions, identical except in concentration, E.M.F.'s are set up which, within certain concentration limits, are predicted by the Nernst equation $E = (RT/F) \log a_1/a_2$. After discussing the results obtained—for example, with mixtures of salts, or pure solutions of salts having a common cation and different anions—Dr. Kressman concluded from his work that, within certain limits, the electrodes are useful for measuring the activities of ions in solution of salts, provided they contain one cationic species only.

Dr. Fairbrother next gave a review of the work of Prof. H. G. Cassidy (Yale) on electron exchange polymers as oxidation-reduction systems. Quoting a letter from Prof. Cassidy, he stated that the material described (*J. Amer. Chem. Soc.*) was largely dimer and trimer, believed to be produced by a chain-terminating type of reaction of the Diels–Alder class. In more recent work, yet to be published, high polymer has readily been obtained by acetylating the monomer first, polymerizing in the presence of benzoyl peroxide, and then hydrolysing to yield polyvinyl hydroquinone which can be oxidized and reduced. The titration curve obtained was 'smeared out' in that it showed a greater slope than that of pure hydroquinone. This has been ascribed to the statistical effect of having many oxidizable groups with slightly different energies (due to their fixed location on the chains relative to other groups). Several co-polymers have been made and also cross-linked polymers to bead form.

A written contribution from Prof. M. G. Evans (University of Manchester) on possible interesting future developments with such resins was then quoted by Dr. Fairbrother. Prof. Evans likened the 'smearing out' effect to that obtained on titration of polyelectrolytes of acid or basic resins, and arises from the same causes. He pointed out that the fixing of the centres may increase the concentration of the semiquinone forms and recalled the early work of Knorr, who found that oxidation-reduction systems adsorbed on protein and cellulose structures appeared to lead to more stable semiquinones. The possibility is opened up of studying, in more detail than previously possible, the specific reactions of such entities, and it is not to be forgotten that the attachment of prosthetic groups to the protein moiety may lead to similar effects. In writing of the relative positions of the groups, Prof. Evans also referred to the possibility of studying co-operative effects, saying that if one could synthesize a resin of which the oxidation-reduction levels formed a band characteristic of the whole structure, one could imagine a process occurring at one end of the structure influencing a coupled oxidation-reduction at a considerable distance away, an interesting possibility which may arise in biological systems. Finally, he commented that the juxtaposition of two reacting centres might speed up oxidation-reduction reactions involving the simultaneous transfer of two electrons, which are normally slow, and there might be an effect similar to that of catalyst structure where a match of pattern becomes important.

Prof. Davies then briefly summarized the applications that had been discussed and pointed out that they ranged over the whole field of the design and utilization of synthetic high polymers for their chemical properties. The term 'ion exchange' has already been outgrown, and many new developments may be anticipated; electron-exchange resins are a subject of interest, and so are specially selective resins, designed to pick out one substance from a high concentration of other ions. Also, the advantage of a column procedure in pushing an equilibrium to completion can be exploited in directions other than in ion exchange—for example, in dissolving sparingly soluble salts or in the chemistry of comparatively stable complex compounds. The possibility of designing materials in which the number, kind and spacing of reactive groups can be predetermined offers a range of models to the theoretical colloid chemist and to the biochemist, who may find the catalytic properties of such materials to be of special interest. Finally, Prof. Davies said, the behaviour and use of ion exchangers in non-aqueous solvents is a subject overdue for development, and may result in laboratory applications of quite a novel kind.

In the concluding discussion Dr. Glueckauf stated that other work by Dr. Barker corroborated the findings of Dr. Kressman on ion-exchange membrane potentials of alkali solutions. Deviations from the theoretically expected potential slope, as yet unexplained, were, however, observed for calcium chloride solutions. Dr. J. D. Bu'Lock, referring to Prof. Cassidy's work and Prof. Evans's speculations on possible biological analogues of electron exchange polymers, directed attention to naturally occurring materials of this type. He cited, for example, melanin, an animal pigment which is a cross-linked polymer of indole-5 : 6-quinone, individual units of which should have different redox potentials, the overall effect being a smoothing-out of the oxidation-reduction curve of the polymer. Natural melanin is bound to protein, forming granules associated with various enzymatic activities. Dr. Bu'Lock suggested that one function of melanin and similar natural products is to provide a suitable environment for the operation of enzymes by a kind of redox buffer mechanism.

INTERNATIONAL SCIENTIFIC RADIO UNION

THE tenth General Assembly of the Union Radio Scientifique Internationale (URSI) will be held in Sydney, Australia, during August 11–23. Of the previous nine meetings of the Union, all have been held in Europe except the second, which took place in Washington in 1927. At the previous General Assembly of the Union, held in Zurich in 1950, Sir Edward Appleton was elected president of the Union and also its delegate to the parent body—the International Council of Scientific Unions. The other officers of the Union appointed at Zurich were: Dr. J. H. Dellinger (U.S.A.), Father P. Lejay (France) and Dr. D. F. Martyn (Australia) as vice-presidents, Prof. Ch. Manneback (Belgium) as treasurer, and Eng. E. Herbays as secretary of the Union, with headquarters in Brussels.

The scientific work of the Union is organized under seven commissions, the titles and presidents of which are as follows: (1) Measurement and Standardization, Dr. J. H. Dellinger (United States); (2) Troposphere and Wave Propagation, Dr. C. R. Burrows (United States); (3) Ionosphere and Wave Propagation, Sir Edward Appleton (Great Britain); (4) Terrestrial Atmospherics, Prof. H. Norinder (Sweden); (5) Radio-Astronomy, Dr. D. F. Martyn (Australia); (6) Waves and Circuits, Prof. B. van der Pol (Director, C.C.I.R.); (7) Electronics, Dr. G. Lehmann (France).

The British National Committee for Scientific Radio is organized under the auspices of the Royal Society as a constituent member body of the Union Radio Scientifique Internationale. This Committee has nominated the following British delegation to the forthcoming general assembly, the numbers of the commissions to which they are specially responsible being indicated in brackets: Sir Edward Appleton (president), Dr. W. J. G. Beynon (3), Mr. J. A.

Ratcliffe (4 and 7), Mr. F. G. Smith (5 and 6), Dr. R. L. Smith-Rose (1, 2 and Executive Committee).

It is understood that Profs. S. Chapman and H. S. W. Massey will also attend the meeting in Sydney by special invitation.

In accordance with established procedure, the various national committees will submit reports to the General Assembly reviewing the advances made within their own countries in each of the fields of research indicated by the seven commissions. As the results of this work may have an important bearing on associated scientific fields and also on the practice of radio communication, the Union is represented on several other international scientific bodies and also on the appropriate study groups of the Comité Consultatif International des Radiocommunications (C.C.I.R.). This arrangement forms a very satisfactory liaison whereby the fundamental problems confronting the practical radio engineer are brought to the notice of the astronomer, meteorologist and radio-physicist, and whose results can be quickly applied to communications technique.

BRITISH CAST IRON RESEARCH ASSOCIATION

By Dr. J. G. PEARCE, O.B.E.

Director

A FURTHER stage in the progress of the British Cast Iron Research Association was reached on July 2 when the president, Dr. J. E. Hurst, formally opened some extensions additional to those previously reported (*Nature*, 166, 261; 1950). These include chemical and spectrographic laboratories, sands laboratory, heavy stores, and accommodation for operational research, development, and work on foundry atmospheres. A fuels and furnaces building is under construction.

The spectrographic laboratory houses a quantometer, an American direct-reading spectrograph, which is channelled to permit estimations of twelve elements occurring in the cast iron alloys, and which is expected to record the elements spectrographically determined in normal material within one minute. The instrument comprises a high-precision source unit built to reproduce almost any type of electrical discharge, a spectrometer measuring through a photoelectric cell system, and a console recording the photocell current through an electronic system. The use of the instrument was demonstrated, although it is not yet fully calibrated. The technique for the spectrographic determination of elements in cast iron was published by the Association in 1948, its application to the less common elements in 1949, and to foundry slags in 1952. It is anticipated that it may be possible to determine both carbon and also phosphorus (not usually determinable by spectrographic analysis), the only element of those normally required that is still incapable of spectrographic determination being sulphur.

It is not practicable to review in detail the whole of the work accomplished and in progress; but some indication of its scope is given by the fact that during the past two years the Association's *Journal of Research and Development* has published seventy-nine reports, including reports presented to a number of conferences held for members during this period.

The establishment of practical foundry processes since 1948 for producing nodular graphite in the as-cast state by means of cerium or magnesium is now a matter of history. Certain difficulties in effecting perfect nodulization by magnesium, thought to be due to interfering elements, have now been resolved. The Association has established the subversive elements concerned, the range beyond which they are troublesome, and that their ill effects can be removed by the use of cerium in conjunction with magnesium. The Association's research manager, Mr. H. Morrogh, has recently received the McFadden Gold Medal of the American Foundrymen's Society for his work in developing nodular graphite iron. These processes have raised very difficult analytical problems for both the chemist and the spectrographer, on account of the very small amounts concerned, not only of the elements used for securing the nodular structure, added and residual, but also of the interfering elements. The vacuum fusion method is employed for the determination of gases.

An investigation into the fluidity of cast iron has been completed, and active work is proceeding on the vitreous enamelling of cast iron, on chilled irons, and on shrinkage and porosity, these latter defects being studied with the aid of gamma rays.

In the field of moulding sands, the emphasis has moved to a study of the properties at elevated temperatures, at which, of course, they are used in practice. Special apparatus has been acquired for this purpose from the United States, and the Association has designed and built its own apparatus for evaluating the stress–strain characteristics of sand aggregates, both at ordinary and at elevated temperatures, and has already related the results to certain common defects due to sand. High-frequency heating is used for giving temperatures required before the sand bond can be affected by the heat. The property known as 'flowability' is being studied, and considerable work has been done on the use of synthetic resins as bonding materials. These resins are used in the shell-moulding process, which has excited considerable interest in foundry circles, the normal mould being replaced by a thin shell of resin-bonded silica sand.

Progress has been made on the study of foundry atmospheres, particularly with reference to the presence of toxic gases and the measurement of dust and dust movement; in particular, the conventional system of hood-extraction used on pedestal grinders, commonly used in foundries for cleaning castings, has been shown to be entirely inadequate. A design has been evolved by the Association, involving the use of high-velocity air streams above and at the side of the working area, using less power than the normal system, and keeping the breathing zone of the operator clear of dust to a remarkable degree. Co-operation with manufacturers is being arranged.

The Operational Research Team set up in 1950 for visiting foundries with the object of recommending steps for promoting production efficiency has now made more than two hundred visits and collected considerable information. The iron-founding industry is operating in the United Kingdom at a record level of output, approaching 4 million tons of iron castings per annum, employing 150,000 people, and the output per man per annum has increased materially in recent years, by some 28 per cent since 1945 and some 13 per cent since 1948, in spite of difficulties relating to raw materials and personnel.

LACE RESEARCH ASSOCIATION

NEW CENTRE AND LABORATORIES

THE new centre and laboratories of the Lace Research Association at Glaisdale Drive, Bilborough, Nottingham, were formally opened on May 15 by Sir Cecil Weir, and after the ceremony a large number of members of the Association and their guests inspected the work being carried out in the laboratories.

The lace industry of Great Britain is a small but highly specialized, and economically important, industry situated mainly in Nottingham and the surrounding districts; all types of lace are manufactured there, but centres are also to be found near Kilmarnock in Scotland, where the product is lace furnishings, and in the west of England, where plain nets are made. There are very few large firms, the industry consisting in general of small unit firms, some three hundred in number, and the average size is of the order of ten machines. The working force varies between ten and fifteen thousand employees, of which, compared with the other textile industries, a very high proportion is made up of male workers. The conversion value of lace from the raw fibre to the finished fabric is exceedingly high; the trade is worth £10–15 million a year and is concentrated mainly on the export market, certain sections exporting as much as 98 per cent of their products.

The industry consists of six separate branches manufacturing the following types of product: plain net section—all types of plain and figured nets, including dress nets, tulle, mosquito nets, sand-fly netting, etc.; leavers lace section—fancy laces, hair nets, veilings, trimming laces, etc.; lace furnishings section—curtains, table and bed furnishings, etc.; warp lace section—lace produced on a multi-thread warp lace knitting-machine; barmen section—narrow lace and braiding; and embroidery section—pattern lace produced on multi-needle 'schiffli' machines, either on a base of plain net or on a dissoluble fabric. Nearly all the common textile fibres, both natural and synthetic, are used, or can be used, in the industry, but the principal fibre is, of course, cotton. An important subsidiary part of the industry is that concerned with the dyeing, dressing and finishing of lace; these operations are confined to a small number of firms which have the necessary specialized skill, experience and machinery.

The building of lace machines is a highly specialized branch of engineering, and Nottingham is naturally the world centre. In general, the machines are very large, those in the leavers section of the industry being of the order of 200 in. in width, while in the lace furnishing section there are several producing lace of up to 480 in. in width.

The idea of setting up a research organization for the lace industry was first mooted in 1943, and in March 1944 a research committee was formed by the Federation of Lace and Embroidery Employers' Association. From this development a Lace Federation Research Council was started, which was recognized by the Department of Scientific and Industrial Research as a grant-earning body, and a small research staff was assembled in temporary premises in Nottingham. After further discussions with all the interested trade bodies, it was decided to take advantage of the Industrial Organization and Development Act and to raise money for the formation of a research organization by means of a statutory levy from all the manufacturing sections of the industry. The Lace Research Association was finally incorporated in October 1949, and took over, in expanded form, the functions of the Lace Federation Research Council. The Association is financed in part by the proceeds of the statutory levy, in part by subscriptions and in part by a government grant based on the income from industry. Generally speaking, it is very well supported by the trade, and its total basic income is of the order of £17,000 a year.

The new building of the Association consists of administrative and laboratory space amounting to approximately 3,800 sq. ft. The front portion contains the library and council room, director's office, general office and textile-testing room. In the laboratory wing are physics and chemistry laboratories, a dark room, engineering workshop, operational research section, store rooms and offices, and a small canteen and kitchen; this wing is built so as to allow for future expansion, the partitioning being easily altered, and running below the main corridor is a trench carrying all the necessary services, with subsidiary trenches into the individual laboratories. To the rear of the site is a separate building with floor space of 2,000 sq. ft. which holds full-scale narrow-width lace machines and certain auxiliary equipment, and in which experimental and development work on the production side may be undertaken; this building is well insulated and is electrically heated with thermostatic control to maintain a steady temperature. The research work in the laboratory wing has up to now been chiefly concerned with two problems. In the first, a new type of Jacquard string known as 'Lacra' string has been developed which does not change appreciably in length with varying humidity (caused by changes in the weather). These strings are of high-quality linen thread and are used in the Jacquard pattern-forming mechanism of lace-furnishing machines. As the strings are of different length, a certain percentage change due to variation in the humidity will cause different overall changes in length and the pattern will be distorted. The new string has now been in service on a number of machines for some time and is proving highly successful. The other research development has been the production of a new lubricant in place of the powdered graphite normally used for lubricating the fine working parts of a lace machine. Graphite has the disadvantage that, being black, it causes considerable dirt in the factory and soils the lace. A new lubricant, the composition of which is at present a secret, has been developed which allows the production of fabrics which are quite white.

As might be expected, a cordial spirit exists between the research staff, headed by J. C. MacCallum as director of research and secretary of the Association, and the University of Nottingham. Three Nottingham professors serve on the council of the Association, and one of them, Prof. L. F. Bates, is vice-chairman of the Research Control Committee. Relations are also maintained with the Nottingham and District Technical College. This co-operation between the research organization of an industry that has a very strong regional background with the educational and technical-training services of that region is certainly a very happy feature of the Association, and it augurs well for the quality of the scientific and technical work that can be expected from the new laboratories.

New Procedures for Resolution of Racemic Substances

EXCEPT for Pasteur's original procedure of sorting crystals by hand, the methods practised or suggested for the preparation of substances in optically active form depend on the use of a dissymmetric substance in one of its enantiomorphous forms or on the application of some dissymmetric influence. A recent extension[1] of the hand-sorting process does not require the use of *d*- or *l*-materials or sorting of crystals by enantiomorphous faces. It has been applied only to trithymotide, a substance of molecular constitution lately elucidated[2]. A second extension now applies to a range of substances.

In the first method, a racemic substance forms a crystalline molecular compound with an optically *inactive* substance. The van der Waals forces that normally hold the *d*- and *l*-molecules together as a crystalline racemate are overcome in a rearrangement involving the second component. Instead of *dl*, there crystallize from the solution *Ml* and *Md*, where *M* is the optically inactive substance. This has been found with trithymotide, which forms a series of molecular compounds $2C_{33}H_{36}O_{6}.M$, where *M* may be benzene, chloroform or a large variety of other substances. Most of these molecular compounds are spontaneously resolved.

The optical activity is demonstrated by the growth of one large crystal or an equivalent crop of crystals all derived from the same seed. No enantiomorphous faces develop; but the crystal is known from X-ray diffraction experiments to belong to an enantiomorphous space group and to contain trithymotide molecules of one hand only. Its solution rotates the plane of polarization of light. The trithymotide racemizes rapidly in solution, and therefore the slow growth of a single crystal or homogeneous crop may be controlled so that all the trithymotide is removed in the *d*- or *l*-form, depending on the nature of the seed. Similar resolutions, not necessarily accompanied by racemization, may be expected. When a *dl*-substance forms a crystalline molecular compound with an optically inactive substance, *d*- and *l*-molecules may enter in equal numbers into the structure, and in this case it will not be resolved; but since to form any molecular compound the normal mode of union of *d*- and *l*- must be disturbed, the chance of spontaneous resolution is increased. Any molecular compound that a *dl*-mixture may form therefore seems more likely to be spontaneously resolved than its parent substance.

The second method is suggested by the behaviour of trithymotide described above. The closely related crystal structures of its molecular compounds contain as the second component such varied molecules as carbon disulphide, benzene, ethanol, *n*-propyl iodide or chloroform, and retain this sometimes volatile component very tenaciously. In this they resemble the clathrate type of compound[3], and the structure must consist of an arrangement of trithymotide molecules enclosing a set of cavities. Whether these spaces are closed or open and whatever their precise form may be, the surrounding molecules, which are all *d*- or all *l*- in any one crystal, impose on the cavities a form which is not identical with its mirror image. If, therefore, trithymotide is crystallized from a solvent which is itself a *dl*-mixture and forms with it a molecular compound similar to those discussed above, the cavities of any one crystal will enclose preferentially the *d'*- or *l'*-form of solvent molecule. Any process for separating the *d*- and *l*-trithymotide should separate *d'*- and *l'*- simultaneously.

The process has been applied to resolve secondary butyl bromide. In one experiment a single crystal was grown and in others homogeneous crops were developed from a single seed crystal by repeated division and growth. The crop when dissolved in chloroform showed a large — rotation due to trithymotide. This decayed rapidly through racemization and left a much smaller permanent — rotation due to the secondary butyl bromide.

With trithymotide the method is applicable to a range of substances; but it may be expected to fail with molecules which are too large for the cavities. It could be extended by the discovery of substitutes for trithymotide. Where it is applicable this method of resolution has advantages that may be of importance. Chief of these is that no chemical reaction is involved in the process and no change of configuration can occur. Since sorting is on the basis of molecular shape and space requirements only, there is no need for a reacting group in the molecule. It could, for example, be applied to paraffins. By suitable modification very small amounts of material may be separated. The optical rotation initially observed when a crystal of the molecular compound is dissolved is due to the trithymotide, and may be hundreds of times greater than that of the resolved substance. Observation of the sense of this initial rotation therefore will provide a means of sorting a quantity of material too small to show its own rotation. Still smaller amounts might be handled in mixtures with a carrier solvent. If both carrier and solute enter into the molecular compound formation, sorting by any process should resolve the rare constituent which occupies a few of the cavities. In the special case where the carrier solvent is *d*- or *l*-, only one of the enantiomorphous crystals can develop and no sorting is necessary. From one known absolute configuration of a molecule that is enclosed by trithymotide, and a detailed structure determination, it is possible in principle to determine the absolute configuration of the cavities corresponding to each enantiomorphous form of the crystal. These being known, the absolute configurations of some other molecules could be deduced from observation of the form of trithymotide with which they combined to form the molecular compound.

Both the methods show how spontaneous production of unequal amounts of *d*- and *l*-forms can occur, and illustrate the preferential incorporation of one form in a growing structure. It is possible that somewhat similar processes may be responsible for the original dissymmetry in the chemistry of living matter and for its perpetuation.

Natural Moisture-content, Porosity and Compaction of Clayey Deposits

It seems desirable that attention should be directed to the very discordant figures for porosity (or void-ratio) of clayey sediments that are yielded by the two different methods of determination that may be adopted, namely, by direct measurement or by calculation from the natural moisture-content. I cannot but think that the discrepancies must have been commented on during the past two decades as knowledge of natural moisture-contents steadily grew; but my inquiries have failed to produce any reference to a published discussion of their implications.

In the following paragraphs the symbols m and n are those used in geotechnical (soil-mechanics) laboratories, m for the natural moisture-content expressed as grams of water per 100 gm. of solid dried to constant weight at 105–110° C., and n for the porosity calculated from m and expressed in the usual manner as the percentage of the total volume occupied by voids. The symbol P is retained for the porosity determined directly by the standard methods. The void-ratio e is the volume of voids to the volume of solid.

The evaluation of m presents no difficulties; but precautions are necessary to ensure that the samples when tested are as nearly as possible in their natural 'undisturbed' condition (in the engineering sense). Weathered or obviously fissured samples are rejected. Sediments lying below the ground-water table are known to be, with few exceptions, saturated down to a considerable depth, although the precise limit is in doubt. All the samples here referred to came from this zone of saturation.

A small but representative selection of values of m, n and P for some British clayey sediments is given in the accompanying table.

	m	n	P
Pleistocene bedded clay	50	57 per cent	31 per cent
Tertiary clays	28	48	29
Upper Cretaceous Gault	29	44	24
Jurassic, Lias	22	37	24
Triassic, Keuper	12	24	12
Coal measures, shale	18	26	10

By way of contrast to the discordant values shown in the last two columns, the results for n and P in the case of a fine-grained calcareous material such as the Upper Chalk reveal no discrepancy. The mean of a number of values obtained by different investigators with samples from various parts of the country is closely 44 per cent for both n and P. It will be observed that this figure falls into its appropriate place in the age-sequence, between the Tertiary clays and the Gault, in the column for n, but not in that for P.

Since the determinations of m and P for sediments from other European countries and from America, so far as I have been able to trace them, are of the same order of magnitude, horizon by horizon, as those listed in the table, and since the procedure followed is similar, there seems no escape from the conclusion that the standard method of directly determining porosity is not suitable for materials containing an appreciable quantity of clay. It is not feasible to allow sufficient time in the laboratory for the restoration of the structure which previously existed in or around the clay-mineral lattices but which was destroyed when the samples were dried.

It should be noted that the volume-shrinkage caused by drying of the test-specimens seems to be inadequate, at least in most cases, to account for the difference. Even if it did so, the objection to the use of the low P values still remains.

That such low values should have been recorded for P will probably not surprise those familiar with the physical changes in clayey materials (for example, loss of plasticity, lowering of liquid limit, increase of grain-size, etc.) produced after even short periods of air-drying.

The porosities vary, of course, according to which particular clay-mineral species is dominant. In due course, we may hope to compile a table for each dominant species. The few figures that are available for montmorillonoid clays indicate that they will fall into a separate series with values of n much higher (as their swelling capacity would suggest) than those in the above table. Passing reference may also here be made to the abnormally low porosity of boulder clay, first discovered by H. C. Sorby and ascribed by him to exceptionally high compression, possibly by ice-load. The determinations of m have confirmed his observations. An average figure for m is 15, whence n is 28 per cent, Sorby's value for P being 24 per cent. The discrepancy here is smaller than in the case of the other clays mentioned, possibly because of the very different mineralogical composition, the quantity of silt and rock-flour in the matrix being usually considerable.

From the values of P set out in the table, and from other similar direct determinations by the standard methods (for example, on air-dried cuttings from deep well drilling) the void-ratio e appears to be only a third to a half its true value as calculated from m. If additional records confirm this, many inferences that have been drawn from the erroneous figures for e will need to be revised, and calculations relating to depth of burial, gravitational pressures, compaction, bulk-density and volumes of sediments may require substantial adjustment.

Many other interesting problems are presented by the records of m that have already accumulated. Since these are all too few, however, it is to be hoped that full advantage will be taken of the exceptional opportunities for collecting and testing clayey sediments at present afforded by numerous engineering undertakings and programmes of exploratory and other borings distributed widely throughout Great Britain.

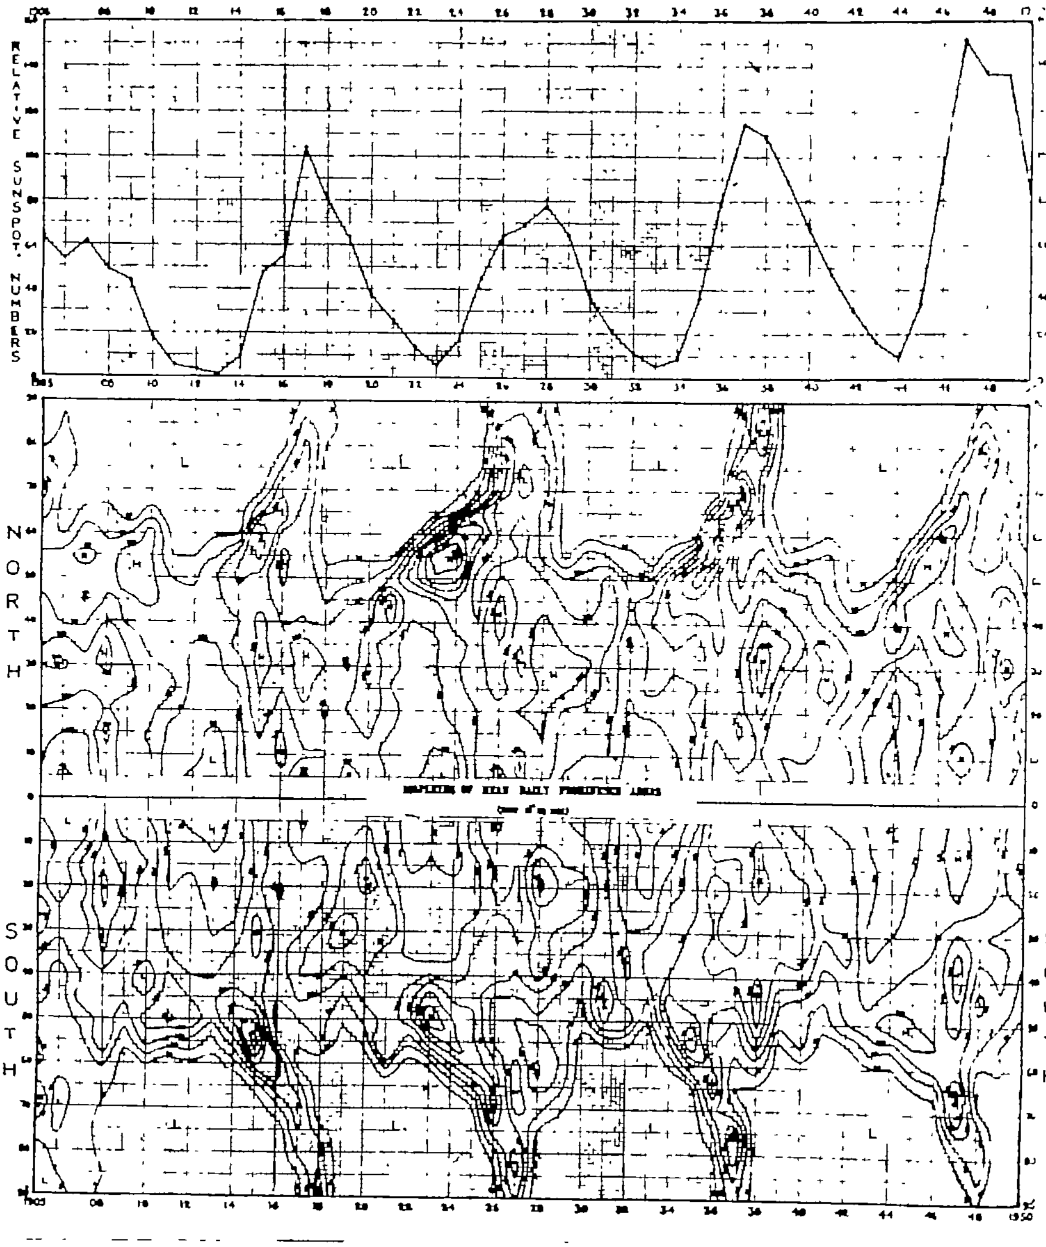
Prominence Activity and the Sunspot Cycle

The relationship that exists between the distribution and frequencies of prominences at the limb of the sun and the sunspot cycle has been discussed by several workers[1]. The most outstanding feature is the existence of two distinct zones of prominence activity in each hemisphere. The low-latitude zones extending from the equator to about 50° are always present, although prominence activity in these zones is least at the epoch of sunspot minimum. The high-latitude zones have a different life-history. Prominence activity in these zones drops very suddenly and becomes quite inconspicuous shortly after sunspot



maximum. About four years thereafter, a centre of activity develops at about latitude 45°–50°. The activity undergoes a rapid increase and at the same time the prominences extend to higher latitudes. The high-latitude zones become fully developed at the epoch of sunspot maximum.

Photographic observations of solar prominences in the *K* line with the spectroheliograph were commenced at Kodaikanal in 1905. The material available up to date covers four sunspot cycles. The Kodaikanal data for the period 1905–14 have been discussed by Mr. and Mrs. Evershed, while the data for the period 1905–28 have been discussed by W. Moss. Half-yearly summaries of prominence observations are published in the *Bulletin of the Kodaikanal Observatory*.

From the mean daily profile areas of prominences computed for each 5° latitude zone, I have prepared the accompanying diagram, which brings out strikingly the relationship between prominence activity and sunspot cycle during the period 1905–50. The contour lines are drawn at intervals of 50×10^{-3} sq. min. of arc of prominence area. Regions of maximum activity are marked *H*, and those of minimum activity *L*. There is some resemblance between this diagram and the well-known 'butterfly diagram' of Maunder. Attention may be directed to an interesting point brought out by this diagram. It is well known that the sunspot maximum of 1947 is one of the highest on record. However, prominence activity has been much less during the latest sunspot cycle as compared with the two previous cycles. The diagram also shows that the region of most intense prominence activity on the sun occurs at about latitude 50°–55° in both hemispheres some three or four years before sunspot maximum.

A detailed discussion of the results of prominence observations made at Kodaikanal during 1905–50 will be published in the *Bulletin of the Kodaikanal Observatory*.

Meson Masses

THE classical electron radius r_e is defined by $e^2/r_e = m_e c^2$. A sphere of constant density with radius r_e possesses a radius of gyration $r_g = (0\cdot4)^{1/2} r_e$. The energy eigenvalues of the rigid rotator are not yet known in the extreme relativistic region; but there one can quantize with integers k as for circularly polarized photons: thus $r_k p_k = k\hbar$. For $k = 1$ and $r_1 = r_g$ it can be deduced that:

$$m_1/m_e = p_1/m_e c = \hbar/m_e c r_1 = \hbar/m_e c r_e (0\cdot4)^{1/2} = 137 \times 1\cdot58 = 216\cdot6. \quad (1)$$

Thus the first rotation level compares with the first meson mass 212 m_e.

The mass of the π-meson requires $r_g = \frac{1}{2} r_e$. This is true for a disk. The non-relativistic eigenfunction P_1^1 consists of a section through the axis. In the extreme relativistic region it will contract and may indeed degenerate into a disk rotating about an equatorial axis.

Levels with $k > 1$ are not impossible. But it seems that the observed higher meson masses can be approximated better by quadratic relations. These can be derived, for example, if one assumes that a sphere with radius r_e can contain n rotators in a row, with radius $r_n = r_e/n$. According to (1), one rotator with radius r_n has a mass $n m_1$. This leads to a total mass $m_n = n^2 m_1$, if all n rotators are of the same kind ($r_g = 0\cdot632 r_n$ or $r_g = \frac{1}{2} r_n$, and $k = 1$). One obtains the following masses:

	$P_{1,0}$	$P_{1,1}$	$P_{2,0}$	$P_{2,1}$	$P_{2,2}$	$\Delta_{3,0}$	$\Delta_{3,1}$	$\Delta_{3,2}$	$\Delta_{3,3}$	$P_{3,0}$	$P_{3,1}$	$P_{3,2}$	$P_{3,3}$	$P_{4,0}$
Calc.	216·6	274	866	951	1,036	1,400	1,523	1,647	1,771	1,949	2,121	2,293	2,466	3,464 m_e
Obs.	212±5	275	796	967	1,125	1,370	1,510				2,203			
	μ	π	V_1	τ	$\varkappa_1$	$\varkappa_4$	$\varkappa_1$				V_1			

The systems are called $P_{n,m}$. The first index specifies the number of rotators contained in the sphere; the second suffix indicates how many rotators possess $r_g = \frac{1}{2} r_n$. The same principle allows the arrangement of three rotators in an equilateral triangle (called Δ), or of four in a tetrahedron (T) within a sphere of radius r_e.

The first seven levels of this scheme seem to have been observed[1]. V_1 compares with the mean of P_3 or T_4 ($T_{4,2}$ = 2,183 m_e). $\varkappa_1$ = 1,510 or 1,550, according to Von Friesen. The observations by Leighton *et al.*[2] can be taken as further evidence for masses $P_{2,0}$, $P_{2,2}$ and $\Delta_{3,1}$.

Incidentally, the proton mass can be obtained if two rotators of the system $\Delta_{3,3}$ gyrate around a twofold symmetry axis. This gyration may, as in ortho-hydrogen, be stabilized by spin symmetry.

The radius r_e can be interpreted as the range of a force with a potential steep enough to balance the centrifugal force due to rotation.

Though the present rotator scheme can represent only a simplified picture of the true eigenfunctions, it already gives the masses of the μ, π, V, τ and ϰ-mesons and has features (symmetry characters, etc.) which should be contained in a final theory.

These results were reported originally at the Bristol Conference on Heavy Mesons, held during December 18–20, 1951.

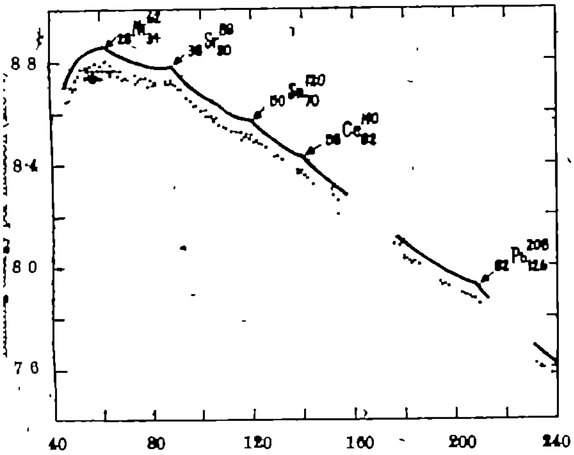
Evidence for Nuclear Shells from Atomic Mass Measurements

THE successful manner in which the single-particle model of the atomic nucleus has accounted for many nuclear properties is well known to those who follow developments in nuclear physics. This model, which pictures nuclei as constituted of shells of protons and neutrons, predicts that closed shells should be exceptionally stable configurations. Both experiment and theory (in that order) have indicated that such closed shells occur[1] with 2, 8, 20, (28), 50, 82 or 126 protons or neutrons. In addition to these primary 'magic numbers', there are predicted a number of secondary ones, marking the closure of sub-shells; but the location of most of these is debatable. It is to be expected that certain mass effects are associated with the closing of these nuclear shells, and it is with this subject that the present communication is concerned.

For some time we have been making mass spectrographic measurements of the masses of many of the heavy nuclides, with the view of studying the gross features of the binding energy per nucleon curve. Descriptions of portions of this work have appeared in the literature. We are taking this opportunity to present briefly the significant results of our investigations to date, some of which are based on unpublished work while others appear only when the data are examined *in toto*.

In the accompanying graph, the binding energy per nucleon is plotted against mass number for approximately 115 of the heavier stable nuclides ($Z > 21$). About half these values have been obtained mass spectrographically, while the remainder have been computed from these using disintegration transmutation and microwave absorption data. On this plot the completion of a nuclear shell should be indicated by a sudden change in the slope, in keeping with the view that a completed shell represents an exceptionally stable configuration to which additional nucleons are rather loosely bound. The fact that such sudden changes in slope are found experimentally can be seen from the graph. Attention will now



Curve of binding energy per nucleon for stable nuclides with $Z > 21$

be directed to certain of these breaks in the curve which have special significance.

(1) There is the well-known break in the curve occurring at $_{82}\mathrm{Pb}^{208}_{126}$, presumably due to the completion of the 82-proton shell *and* the 126-neutron shell. The change in nuclear stability in the lead region was observed[3] by Dempster many years ago and is, of course, borne out by the fact that all nuclides heavier than Pb^{208}, with the single exception of its neighbour $_{83}\mathrm{Bi}^{209}_{126}$, are radioactive.

(2) Clearly shown is the sudden break in the region of mass 90, which is to be attributed to the closure of the 50-neutron shell. This sudden change n slope appears to occur at $_{38}\mathrm{Sr}^{88}_{50}$.

(3) There is an unmistakable break in the 82-neutron region, probably located at $_{58}\mathrm{Ce}^{140}_{82}$.

(4) The stabilizing effect of the 50-proton configuration has a pronounced effect on the curve, giving rise to a definite plateau which breaks off at or in the neighbourhood of $_{50}\mathrm{Sn}^{120}_{70}$.

(5) The maximum of the curve occurs at $_{28}\mathrm{Ni}^{62}_{34}$. It may or may not be significant that the maximum is located at this particular isotope of nickel, but it is almost certainly significant that it is an isotope of nickel, the proton number of which is 28.

These five features of the curve of binding energy per nucleon against mass number for the heavy masses are now well authenticated. In addition to these, as can be seen in the graph, there are suggestions of other fine structures which need more careful study and, also, there are several unexplored regions. It s gratifying that the present results are concordant with the predictions of the single-particle model. They should be useful in determining the magnitude of the closed-shell contribution to the stability of the nucleus.

It should be noted that A. O. C. Nier and his group at the University of Minnesota and S. A. Goudsmit and his group at Brookhaven have measured[4] many heavy atomic masses in the past few months. The agreement between these recent results and ours is generally satisfactory. The accompanying graph, however, is based, so far as the mass spectrographic work is concerned, on measurements made n our own laboratory. This set of values is more likely to be internally consistent than one compounded from several sources and, also, for a large number of the nuclides shown in the graph, our masses are still the only ones available.

Polarization Field and the Acoustic Modes of Oscillation of Alkali Halide Crystals

IN a recent paper[1], the frequency of the principal lattice oscillation of an alkali halide crystal, in which the lattice of the alkali ions oscillates with respect to the lattice of the halide ions, was calculated on the basis of the simple Born model. It was found that the electric polarization of the crystal that accompanies this oscillation leads to a polarization field of the Lorentz type which tends to increase the relative displacement of the two lattices and has thus a marked influence on the principal frequency. Microscopically, this polarization may be regarded as due to small dipoles located at the lattice points. Because of the small amplitude of the oscillation, these dipoles will be practically point-dipoles, and since they are also cubically arranged, the polarization field will have just the Lorentz value, namely, $4\pi/3$ times the polarization per unit volume. (Indeed, this appears to be the only case where the conditions postulated by Lorentz for obtaining the factor $4\pi/3$ are rigorously satisfied.)

The important part which the polarization field plays in determining the resonance frequency of the crystal is indeed to be expected from other considerations. Let us consider, for example, the dielectric constant of the crystal, and confine attention to the contribution from the relative displacements of the positive and the negative ions, as distinguished from the electronic polarizations of the ions themselves. Then the effect of the polarization field on the dielectric constant may be taken into account in two alternative ways. We may regard the effective field that produces the polarization as consisting of not only the 'field in the medium', but also the polarization field, in which case we obtain a formula of the Lorentz type:

$$\frac{K_e - 1}{K_e + 2} = \frac{C/3}{\Omega_t^2 - \omega^2}, \qquad (1)$$

in which Ω_t is *not* the resonance frequency of the crystal but a certain hypothetical frequency which the crystal would have, had there been no polarization field to affect it. Resonance will occur when the right-hand side of (1) tends to unity, that is, when

$$\omega^2 \to \omega_t^2 = \Omega_t^2 - C/3. \qquad (2)$$

Alternatively, we may regard the effect of the polarization field as confined wholly to changing the hypothetical frequency Ω_i to the actual resonance frequency ω_i of the crystal, in which case we obtain the Drude formula:

$$K_\infty - 1 = \frac{C}{\omega_i^2 - \omega^2}, \tag{3}$$

in which C has the same value as in (1).

The relation between the two frequencies ω_i and Ω_i may also be expressed in the form:

$$\Omega_i^2 = \omega_i^2 \left(\frac{K_0 + 2}{3}\right), \tag{4}$$

or more generally,

$$\Omega_i^2 - \omega^2 = (\omega_i^2 - \omega^2) \left(\frac{K_\infty + 2}{3}\right). \tag{5}$$

The acoustic modes of oscillation also lead to a finite polarization of the crystal, since the amplitudes of the two ions are in general different, as a result of the difference in their masses. Though the polarization now is much smaller than in the optical oscillations, the resulting polarization field is still comparable with the field due to the electrostatic and the repulsion interactions between the ions displaced by the acoustic wave.

We have studied the effect of this polarization field on the low-frequency acoustic oscillations in detail, and we find that the polarization field affects considerably the relative amplitudes of the two ions, but their frequencies remain completely unaffected by it (unlike the optical frequencies). This is very satisfactory, since otherwise the well-known Christoffel relations connecting the velocities of propagation of acoustic waves in the crystal with its elastic constants will be disturbed.

Note added in proof, June 30. Detailed investigations on the effect of the polarization field on the acoustic modes of oscillation have since been published (Krishnan and Roy, *Proc. Roy. Soc.*, A, 210, 481 (1951)).

Direct Calculation of Viscosities of Liquids

In my viscosity equation for liquids[1]:

$$\eta = \frac{hNb}{V^{2/3}(V-b)^{4/3}} \cdot \exp(1{\cdot}091\,\gamma V^{2/3} N^{1/3}/RT). \tag{1}$$

η is viscosity, V is molar volume, γ is surface tension, T is the absolute temperature, h is Planck's constant, N is the Avogadro number, R is the gas constant and b is the volume occupied by the molecules in the liquid state per mole. It was shown that $b \approx 0{\cdot}33\, V_c$, V_c being the molar critical volume, and that b was a function of temperature. It appeared to me that a direct calculation of viscosity was possible if only b could be obtained by a method not involving viscosity, as all other values on the right-hand side of the equation could be independently obtained.

Applying the equation to benzene and carbon tetrachloride, which have widely differing chemical constitutions, gives results shown in the accompanying table. These indicate that although b and are both functions of temperature, $(V - b)$ is practically independent of temperature. An analogou constancy of $(V - b)$ values is obtained with othe normal liquids such as chloroform (8·37), carbo disulphide (0·38), etc. The necessary data for computation have been taken from the Internationa Critical Tables, any data not directly recorded therei having been calculated from reliable formulæ give in the same Tables. The constancy of $(V - b$ observed here is rather surprising in view of the fac that it is contrary to the existing views about th behaviour of liquids. Perhaps the term $(V - b)$ a used here is an oversimplified expression, whic should await further clarification.

Temperature (° C)	$V - b$	$\eta_{obs.}$	$\eta_{calc.}$
Benzene			
0	9·36	9·00 × 10⁻³	8·81 × 10⁻³
10	9·49	7·57	7·57
20	9·56	6·47	6·50
30	9·55	5·61	5·63
40	9·58	4·92	4·95
50	9·64	4·36	4·38
60	9·54	3·89	3·90
70	9·48	3·50	3·50
	Mean 9·52		
Carbon tetrachloride			
7·15	7·13	1·19 × 10⁻³	1·27 × 10⁻³
21·21	7·17	0·95	0·94
35·21	7·21	0·79	0·79
49·51	7·20	0·66	0·66
62·87	7·22	0·57	0·57
74·16	7·25	0·50	0·51
	Mean 7·20		

The next step is to compare values of $V -$ obtained from my equation with those obtained b other methods. A good review of various method for estimating free volumes in the liquid state ha been given by Fowler and Guggenheim[2]. From th coefficient of thermal expansion and the compressibility, for a large number of liquids with non-pola molecules[2], $V - b \simeq 8$ c.c./mole. Such values ar in good agreement with those obtained from m equation for benzene, carbon tetrachloride an chloroform[2], but not for carbon disulphide.

From the formula given by Lennard-Jones an Devonshire[3] and its analogue by Eyring and Hirschfelder[4], Fowler and Guggenheim[2] give for chlorofor at ordinary temperatures, as a typical example $V - b \sim 0{\cdot}44$ c.c./mole. This value is considerabl lower than that obtained either by my equation o from the ratio of the compressibility and coefficien of thermal expansion[2]. But, for carbon disulphide for which $V^{2/3}$ is not much different from that fo chloroform, the value of $V - b$ from the formul under consideration is in good agreement with tha from my equation.

Fowler and Guggenheim[2] describe another metho of estimating free volume from the vapour pressure choosing chloroform at its boiling point as a suitabl illustration, they find $V - b \sim 1$ c.c.

Eyring *et al.*[5] utilize the velocity of sound in liquid to obtain the free volume by a formula which gives for benzene at 15° C., $V - b = 0{\cdot}49$ c.c.

We thus see that the values of free volumes obtaine by different methods are not only not concordan but also they are often widely divergent. However it may be concluded that the values of $V - b$ fro the viscosity of my equation are of a reasonable orde of magnitude.

Viscosities have been calculated from my equatio by using the mean value of $V - b$ empirically deermined from the equation and recorded in the table nd by substituting all the values for the symbols n the right-hand side of the equation. The results hows that the agreement between the calculated and he observed values of η is good provided that $V - b$ correctly chosen. Further, since $V - b$ is found o be independent of temperature, using my equation s the basis, if a reliable value is available for one emperature, viscosity at other temperatures can be alculated directly with a reasonable degree of ccuracy. However, a clear interpretation of the $- b$ term is needed and further work in this con exion is in progress.

Effect of Drying upon the Absorption Spectra of Hæmoglobin and its Derivatives

It was shown by Zeynek[1] that on drying eoxygenated hæmoglobin *in vacuo* at 40°, its haracteristic one-banded absorption spectrum is eplaced by that of a hæmochromogen with two ands at 556 and 528 mμ, the first band being much tronger than the second. On re-introducing water ontaining oxygen, the absorption spectrum of the æmochromogen is rapidly replaced by that of xyhæmoglobin. These important observations were ecently confirmed and extended by Haurowitz[2], who ut forward the view that the formation of this nhydro-hæmoglobin is due to the removal of the ater molecule occupying the sixth co-ordination ond of the iron atom, followed by polymerization f the resulting products, in which the iron of one is nked with the protein of another.

Haurowitz[3] also dried oxyhæmoglobin over phoshorus pentoxide in presence of sufficient air (c. 00 mm. mercury) to maintain the pigment in the xygenated state. Once the anhydrous oxyhæmolobin is formed, it cannot give up its oxygen in a igh vacuum.

Since the iron both of hæmoglobin and oxyhæmolobin is in the divalent state, it would appear teresting to determine the effect of drying upon ethæmoglobin, the corresponding ferric compound.

The methæmoglobin used in these experiments was repared by treating a strong solution of recrystallized orse oxyhæmoglobin in dilute sodium carbonate H ~ 9) with ferricyanide and dialysing against ater until completely free from ferricyanide. A rown solution of acid methæmoglobin (pH $\ngtr 6$) howing a distinct absorption band in the red region about 630 mμ, when dried in a desiccator, gives distinctly red product with two absorption bands, 567, β 534 mμ, of which the β-band is much wider d stronger than the α-band. The red colour and e two-banded spectrum of the dry product are aracteristic of a parahæmatin. On treating this ied product with water it rapidly dissolves, giving a clear brown solution with the absorption spectrum of acid methæmoglobin. On the other hand, fluoride methæmoglobin similarly dried retains its characteristic colour and absorption spectrum with its band at 605 mμ. The same applies to azide-methæmoglobin, except that here the phenomenon is more difficult to observe since the complex shows a certain spectroscopic resemblance to a parahæmatin. Cyanmethæmoglobin can also be dried unchanged under reduced pressure (½ atmosphere) over phosphorus pentoxide and dry potassium cyanide.

The experiments on drying hæmoglobin and methæmoglobin strongly support the view that the sixth bond in the octahedral complex of iron in these compounds is occupied by a molecule of water. In typical hæmochromogen and parahæmatin compounds, both the fifth and the sixth covalent bonds of iron are occupied by nitrogenous groups. It thus follows that on drying hæmoglobin or methæmoglobin the water molecule bound to their iron is replaced by a nitrogenous group in the protein either of the same or, as was suggested by Haurowitz[2], of another molecule of the pigment. In this connexion it is important to note that compounds in which the water molecule bound to iron is replaced by oxygen, as in the case of oxyhæmoglobin, or by fluoride, azide and cyanide ions, as in the case of the corresponding derivatives of methæmoglobin, show no change in their colour and absorption spectra when they are dried.

This study of the desiccation of methæmoglobin thus confirmed the results of our previous experiments on the effects of low temperatures on the absorption spectra of acid and alkaline methæmoglobin, where it was shown that the sixth position around iron in acid methæmoglobin is occupied by a molecule of water[4]. The formation of alkaline methæmoglobin therefore involves the loss of a proton[5] instead of the addition of a hydroxyl ion.

Although we have been able to confirm Haurowitz's conclusion that the dehydrated form of oxyhæmoglobin does not give up its oxygen in a high vacuum, we find that this conclusion is not adequately established by the experiment recorded in his Fig. 3. In fact, the positions and the relative heights of the bands α and β in the curve representing "anhydrous oxyhæmoglobin" indicate that a considerable part of the oxyhæmoglobin had been oxidized to methæmoglobin which, on drying, was converted to globin parahæmatin. When dissolved in sodium carbonate solution, such dry material would yield a mixture of alkaline methæmoglobin and oxyhæmoglobin. That such a mixture was indeed obtained is strongly suggested by the relative heights of the bands in the second curve of the same Fig. 3. By working rapidly we have been able to obtain both the anhydrous oxyhæmoglobin and its solution in carbonate showing the absorption spectrum of pure oxyhæmoglobin. There is therefore no doubt as to the correctness of Haurowitz's conclusion, notwithstanding the experimental results that he has given.

The reversible appearance of a hæmochromogen or a parahæmatin absorption spectrum during the drying of hæmoglobin or methæmoglobin respectively indicates that the drying process is accompanied by some reactions not unlike the reversible denaturation observed for the first time by Anson and Mirsky[6] on hæmoglobin treated with acid or salicylate. Moreover, it is well known that hæmoglobin is much less resistant to denaturation by alkali and acid than is oxyhæmoglobin. A similar difference between methæmoglobin and oxyhæmoglobin can be demonstrated simply by shaking these solutions with chloroform, when only the former is denatured and is precipitated. When the water molecule bound to iron in methæmoglobin is replaced by fluoride or azide ions, however, the pigment acquires resistance to chloroform treatment. These results are exactly parallel to those observed in the desiccation experiments, which demonstrated an increased resistance of hæmoglobin and methæmoglobin to denaturation when their iron-bound water molecules are replaced by oxygen, fluoride or azide.

The reactions taking place during the drying of hæmoglobin and methæmoglobin, although perfectly reversible, appear to be of a more complex nature than the simple polymerization envisaged by Haurowitz[3], and to involve reversible changes in the architecture of the whole hæmoprotein molecule.

Transaminases for Pyridoxamine and Purines

Braunstein's[1] demonstration of the transaminase reaction as a mode of formation of amino-acids has been broadened recently to include a wide variety of transaminases in bacteria[2], animal tissues[3] and plants[4]. In the present communication, we wish to report the formation of compounds other than amino-acids by the transaminase reaction.

Vacuum-dried cells of *Escherichia coli*, strains *B* and Crooks's, were used as sources of enzyme. Extracts were prepared by grinding cells with an equal weight of 500-mesh 'Carborundum', the cell debris removed by centrifugation and the clear, cell-free supernatant used directly, or after fractionation by precipitation with ammonium sulphate, followed by protamine treatment.

Table 1. TRANSAMINASES FOR PYRIDOXAMINE, ADENINE, GUANINE AND CYTOSINE

Reaction volume, 1 ml., containing

M Phosphate buffer, *p*H 8 3	0 1 ml.
Alpha ketoglutarate	25 μ*M*
Amino-donor	25 μ*M*
Pyridoxal phosphate, calcium salt	10 γ
Cell extract	approx. 15 mgm. cells

Incubated 60 min., 37° C. Reaction stopped with 0 1 ml. 100 per cent trichloroacetic acid, 0·02 ml transferred to paper and chromatogram developed with phenol/water (80/20). The μ*M* glutamic acid (*R_F* = 0·36) formed per ml. were estimated from the chromatograms by comparison with the size and density of spots shown by known amounts of glutamic acid

Enzyme and substrate	μ*M* Glutamate formed/ml. from amino-donors				
	No addition	Pyridox-amine	Aden-ine	Guan-ine	Cytos-ine
Extract	0 5	0 5	0 5	0 5	0 5
Extract, α-keto-glutarate	0 5	8	6	6	6
Extract, α-keto-glutarate, pyridoxal phosphate	0·5	8	6	6	6

The occurrence of a series of transaminases in these cell extracts is indicated by the results shown in Table 1. These preparations catalyse glutamate formation from alpha ketoglutarate in the presence of pyridoxamine, adenine, guanine and cytosine as amino-donors. The presence of ammonia does not lead to glutamate formation, thus indicating a transamination reaction. As shown in Table 2, the transfer of the amino-group of pyridoxamine to alpha ketoglutarate is dependent on the presence of the 'transaminase', pyridoxamine, alpha ketoglutarate and pyridoxal phosphate. The reversal of this reaction has been shown to occur with glutamic acid as amino donor and pyridoxal as amino-acceptor.

Table 2. PYRIDOXAL PHOSPHATE REQUIREMENT OF PYRIDOXAMINE TRANSAMINASE

Reaction volume, 1 ml All samples contained 0·1 ml. *M* phosphate buffer, *p*H 8 3, enzyme, and additions as indicated. Substrate and coenzyme concentrations as in Table 1

Additions	μ*M* Glutamate formed/ml.		
	Dried cells, 15 mgm.	Cell-free extract, approx. 15 mgm. dried cells	0 23–0·3 saturated ammon. sulphate fraction, approx. 15 mgm dried cells
None	2	0 5	0
α-Ketoglutarate	2	2	0
α-Ketoglutarate, pyridoxamine	8	6	0
α-Ketoglutarate, pyridoxamine, pyridoxal phosphate	8	8	8

These observations suggest a mechanism of formation and interconversion of the purines and pyrimidines, and a route from pyridoxamine to pyridoxal. The importance of the transaminase reaction as a general mechanism of amino-transfer in living organisms is suggested.

Formation and Breakdown of Pentose Phosphates by Liver Fractions

It has previously been shown in this laboratory that at least two liver factors are necessary for the oxidation of D-ribose-5-phosphate by ammonium sulphate precipitated fractions of horse or rat liver one being an aldolase and the other a dehydrogenase specific for coenzyme II. Ribose-5-phosphate i oxidized most rapidly by a combination of live fractions *A* (0·4–0·5 saturation with ammonium sulphate) and *B* (0·5–0·6 saturation), the forme being richest in glucose-6-phosphate dehydrogenase and the latter most active in splitting ribose-5 phosphate, as judged by the disappearance of pentose using the orcinol method[1]. The breakdown of ribose 5-phosphate, unlike the oxidation, is independent o coenzyme II and oxygen and never proceeds beyond 66–72 per cent disappearance of pentose.

Ketopentose phosphate formation has been detected by the cysteine–carbazole[2] and orcinol nethods, both during the oxidative decarboxylation of 6-phosphogluconate by liver fraction *C* (0·6–0·7 aturation) and during the splitting of ribose-5-phosphate by fraction *B*. This is in accord with Horecker and Smyrniotis[4], who found that a purified 6-phosphogluconic acid dehydrogenase from yeast first decarboxylated 6-phosphogluconate to ribulose-5-phosphate before conversion into ribose-5-phosphate. It would thus now appear that at least three liver factors are necessary for the oxidation of ribose-5-phosphate, namely, a pentose phosphate somerase, an aldolase and a dehydrogenase specific or coenzyme II. It is of interest in this connexion hat crystalline muscle aldolase does not split ibose-5-phosphate.

On attempting to synthesize ketopentose phosphate rom triosephosphate and glycolaldehyde, the same ketopentose-1-phosphate was readily formed both with crystalline muscle aldolase and liver fraction *B*. This presumably is identical with the ketopentose-1-phosphate synthesized by Racker[5] with muscle ldolase and more recently by Hough and Jones[6] with pea aldolase, the latter workers identifying the ketopentose as xylulose. It is oxidized slowly by ombined liver fractions *A* and *B*, the oxidation in he absence of coenzyme II, presumably due to oxidation of glycolaldehyde, being approximately half the ate of the oxidation in the presence of coenzyme II. The ketopentose-1-phosphate is relatively acid-labile, he hydrolysis constant in *N* hydrochloric acid at 00° being 86 × 10^{-3}, in comparison with 2·5 × 10^{-3} or synthetic ribose-5-phosphate.

Although glycolaldehyde is generally assumed to e the C_2 fragment resulting from enzymic breakown of ribose-5-phosphate, experiments with liver ractions do not support this view. Glycolaldehyde as never been detected during the breakdown of ibose-5-phosphate by liver fraction *B* even under naerobic conditions, and does not disappear on ncubating with this liver fraction, although it is lowly oxidized, in the absence of coenzyme I or I, by combined *A* + *B* + *C* liver fractions. Morever, although normally the breakdown products of bose-5-phosphate are rapidly converted into hexose-monophosphate, in the presence of glycolaldehyde no exosemonophosphate is formed but instead the same etopentose-1-phosphate accumulates as is synthesized from triosephosphate and glycolaldehyde.

Most of the ribose-5-phosphate broken down by ver fractions has been accounted for by hexosemonophosphate formation, which has previously been hown to be formed from ribose-5-phosphate by ver[7] and hæmolysed erythrocytes[8]. Hexosemonohosphate has been determined by measuring the xygen uptake on addition of coenzyme II and liver action *A* (rich in glucose-6-phosphate dehydrogenase ut completely inactive in oxidizing ribose-5-phoshate and glycolaldehyde) to heat-inactivated ribose-phosphate digests by liver fraction *B*, and also by measuring the rate of reduction of coenzyme II at 40 mμ either on addition of liver fraction *A* or of a urified *Zwischenferment*[9]. At least 75 per cent of the bose-5-phosphate broken down is converted into exosemonophosphate, fructosemonophosphate being rmed first and gradually converted into glucose-6-hosphate. This is much greater than the 50 per nt conversion which could occur by aldolase connsation of the triosephosphate formed from ribose-phosphate, and indicates that the rest of the pentose olecule must be incorporated. Synthesis of hexoseonophosphate does not proceed via fructosediphosphate, since these liver fractions are devoid of fructosediphosphatase and, moreover, fructosediphosphate is not oxidized at all even by combined *A* + *B* + *C* liver fractions, which actively oxidize fructose-6-phosphate, glucose-6-phosphate and ribose-5-phosphate.

This work will be published in detail elsewhere.

Glucuronide Decomposition in the Digestive Tract

THE discovery of an enzyme decomposing glucuronide in the rumen of the sheep[1] has been followed by the detection of similar enzymes in the large intestine of the horse[2] and in locust crop liquor[3]. It seemed possible that such enzymes are concerned in the digestion of polysaccharides containing β-linked glucuronic acid residues, such as hemicellulose and hyaluronic acid, and a survey was therefore made of their occurrence in different parts of the alimentary tract in various species of animal. Typical results are shown in the accompanying table. It should be pointed out that these results are only of qualitative value, since the enzyme assays were carried out under conditions which are optimal for the sheep rumen enzyme[1], but are not necessarily so for the enzymes from other sources. Moreover, in the rumen, omasum, cæcum and colon, the enzymes may well be of microbial origin, as has been shown for the sheep rumen enzyme[1], and therefore surrounded by membranes of varying toughness and permeability. A further factor which was not controlled was the diet of the animals, some of the material being obtained from the slaughter-house.

In spite of the reservations made above, the results in the table are of considerable interest in showing the occurrence of very active enzymes of this type in the digestive tracts of all species of animal studied. So far as any generalizations are possible, it may be said that enzyme activity was appreciable in the fore-stomachs of ruminants, and very high in the large bowel of all species. Activity was low or lacking in the stomach, abomasum or gizzard. Appreciable activity was frequently noted in the small intestine. This may have been due to secretion of animal tissue β-glucuronidase into the lumen or to sloughing of epithelial cells.

Enzymes from many sources were tested for inhibition by 0·00025 *M* saccharo-1 : 4-lactone. In this concentration, the lactone causes complete inhibition of mouse liver β-glucuronidase, but only 50 per cent inhibition of the enzyme from the rumen of the sheep[4]. In the present experiments it caused

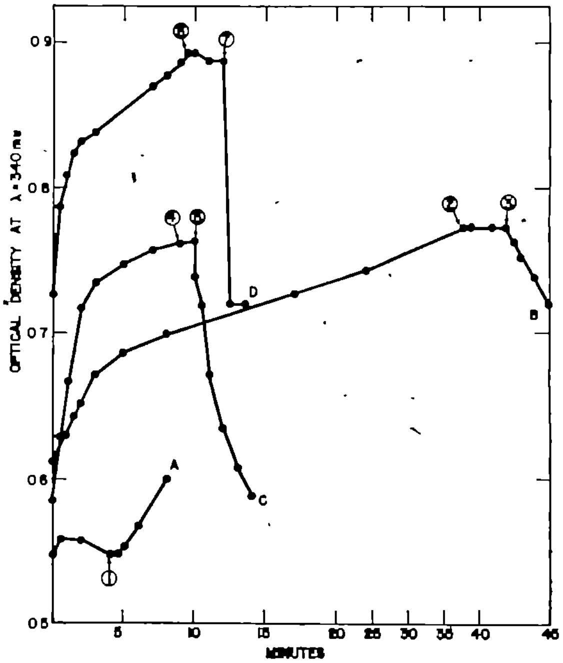
Triosephosphate Dehydrogenase and Glucose-6-Phosphate Dehydrogenase in the Pea Plant

THERE is considerable evidence indicating that the mechanisms of carbohydrate catabolism are the same in higher plants, yeast and muscle[1]. However, it has been reported that mature pea plants do not oxidize triosephosphate[2].

We find that extracts of roots, stems and leaves of pea plants, 16 and 22 days old, prepared by treatment of the tissues with 0·1 M disodium hydrogen phosphate and ammonium sulphate fractionation, contain enzymes catalysing the oxidation of glyceraldehyde-3-phosphate by the pyridine nucleotides. There appears to be two enzymes in stem and leaf, one requiring triphosphopyridine nucleotide, the other diphosphopyridine nucleotide. The enzyme of the root is active only with the latter nucleotide.

Oxidation of the triosephosphate with diphosphopyridine nucleotide does not occur until the extracts are incubated with cysteine even when freshly prepared. Oxidation with triphosphopyridine nucleotide occurs in extracts without cysteine. Both enzymes are inhibited by iodoacetamide, but that requiring triphosphopyridine nucleotide appears less sensitive. The accompanying graph illustrates the activity of the triosephosphate dehydrogenases as indicated by reduction of the nucleotides by glyceraldehyde-3-phosphate. Reactions were run in Beckman quartz cuvettes (d = 1 cm.) with a total volume of 3·0 ml., and readings were made against a water blank. All reaction mixtures contained veronal buffer, pH 8·0, 52 μM sodium arsenate, 60 μM sodium fluoride. Curve A indicates the effect of cysteine on the enzyme requiring diphosphopyridine nucleotide. Curves B–D indicate reduction of the nucleotides by the aldehyde and subsequent reoxidation by means of yeast alcohol dehydrogenase or rabbit muscle lactic dehydrogenase. The slow oxidation of reduced triphosphopyridine nucleotide by means of the alcohol dehydrogenase, which is specific for diphosphopyridine nucleotide (curve B), indicates the presence of an enzyme converting reduced triphosphopyridine nucleotide to the reduced diphosphopyridine nucleotide[3].



Curve A. Effect of cysteine on activity of coenzyme I linked triose phosphate dehydrogenase. 1·5 μM glyceraldehyde-3-phosphate, 0·03 ml. fresh leaf extract, 0·17 μM diphosphopyridine nucleotide. At arrow 1, 12 μM cysteine added.
Curve B. Reduction of triphosphopyridine nucleotide by leaf enzyme. 0·14 μM triphosphopyridine nucleotide, 0·03 ml. of three-week old 40–50 per cent ammonium sulphate fraction of leaf extract. Reaction started by addition of 1·5 μM glyceraldehyde-3-phosphate. At arrow 2, 50 μM acetaldehyde added; at arrow 3, crystalline yeast alcohol dehydrogenase added.
Curve C. Reduction of triphosphopyridine nucleotide by leaf enzyme and reoxidation with lactic dehydrogenase. 0·14 μM triphosphopyridine nucleotide, 0·03 ml. of same leaf fraction used in curve B, 12 μM cysteine. Reaction started by addition of 1·5 μM glyceraldehyde-3-phosphate. At arrow 4, 50 μM sodium pyruvate added; at arrow 5, rabbit muscle lactic dehydrogenase added.
Curve D. Reduction of diphosphopyridine nucleotide by leaf enzyme and reoxidation by alcohol dehydrogenase. 0·17 μM diphosphopyridine nucleotide, 0·03 ml. fresh leaf extract incubated 6 min. with 12 μM cysteine. Reaction started with 1·5 μM glyceraldehyde-3-phosphate. At arrow 6, 50 μM acetaldehyde added; at arrow 7, crystalline yeast alcohol dehydrogenase added

The roots, stems and leaves also possess a glucose- -phosphate dehydrogenase which is active only with :iphosphopyridine nucleotide. This activity is not ffected by iodoacetamide or fluoride but is increased y cyanide. Triphosphopyridine nucleotide reduced y the glucose-6-phosphate dehydrogenase can be -oxidized by the extracts of the leaf and stem with -phosphoglycerate in the presence of adenosine riphosphate.

Since the triosephosphate dehydrogenase requiring riphosphopyridine nucleotide was found only in parts f the plant containing chlorophyll, it is of interest to peculate that it participates only in photosynthesis, hat is, in the conversion of phosphoglycerate to riosephosphate, whereas the other dehydrogenase is oncerned in carbohydrate catabolism. The presence f a glucose-6-phosphate dehydrogenase indicates hat plant tissue may degrade hexose by a mechanism imilar to that of yeast[4] or animal tissue[5].

Full details of this investigation, which was carried ut at Brookhaven National Laboratory under the uspices of the U.S. Atomic Energy Commission, will e published elsewhere.

I am indebted to Prof. E. Baer for a generous gift f the dioxane addition compound of *dl*-glyceraldeyde 1-bromide 3-phosphoric acid. I am also inebted to Dr. Ralph DeMoss for many helpful uggestions.

Glycerol as a Nutritive for *Vibrio choleræ*

IT has been found that glycerol, incorporated in a edium suitable for growing *Vibrio choleræ*, increases he number of organisms yielded. This effect of lycerol is strongly enhanced when phosphates are resent as well. Glycerol, in a concentration of 2·2 er cent (corresponding to 1·5 ml. glycerol per 100 ml. edium), doubles the harvest obtained from a solid asal medium containing 1 per cent peptone and ·5 per cent sodium chloride. Omitting the glycerol nd adding phosphate (0·25 per cent disodium ydrogen phosphate) to the basal medium raises the rop only slightly.

A more than sevenfold yield, however, is due to he combined action of glycerol and phosphate in he concentrations stated above. This manifold nprovement in growth is nearly the same for two ifferent strains used in vaccine production, namely, gawa and Inaba.

It is intended to publish a fuller report of this work lsewhere.

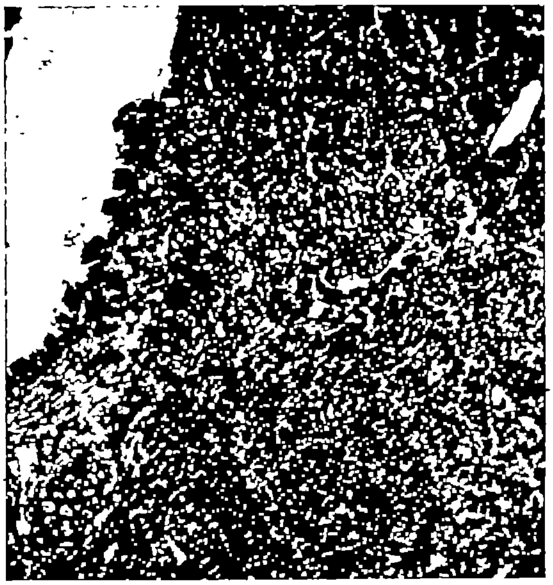
Lepine and Sautter's Disease in Great Britain

THE first guinea pig lung showing symptoms like that of the subclinical virus disease described by Lepine and Sautter[1] was found in Great Britain two years ago. Since that time, examination of guinea pigs from various sources has shown that this condition causing microscopical lung hepatization is widespread in Britain.

As in the cases of Lepine and Sautter, the animals exhibited no clinical symptoms. The only macroscopical change is that the lung is a lighter pink than usual; the hepatization of the lung can only be detected on microscopical examination, and is the sole means of identification.

Histopathological changes observed in the lung can be divided into two groups.

(1) *Peribronchial condensation in the lung.* This is characterized by proliferation and accumulation of a variety of cells, including fibroblasts, reticulocytes, developing cells of the lymphoid series, and a large number of small lymphocytes (see photograph). With reticulum staining, these areas show an abundance of reticular fibres.



Type I condensation (hæmatoxylin-eosin). × 100

(2) This type of condensation is characterized by a thickening of the alveolar wall due to cellular proliferation, involving particularly the capillary endothelium. No inclusion bodies could be detected in any of the condensations, either with neutral red (Duffet) or phloxyn-tartrazin (Lendrum) staining.

Since bacteriological examination was negative, it is logical to assume that the disease was caused by virus. I have been unable to determine whether this condition is identical with that described by Lepine and Sautter; nevertheless, the extent of distribution warrants a more extensive investigation.

My thanks are due to Mr. R. C. James for his technical assistance.

Hyoid Arch of Rhinobatidæ

The skeleton of the hyoid arch of Batoidei has been for many years the subject of discussion by morphologists. Gegenbaur[1] considered the hyoid elements bearing hyal rays and lying posterior to the hyomandibular cartilage to represent the ceratohyal of Selachoidei, which became disconnected from the ventral edge of the hyomandibular and extended upwards behind it. Krivetski[2] and de Beer[3] considered these hyoid elements as pseudohyoid and formed by the fusion of the proximal ends of the hyal rays. Such a phenomenon occurred during the phylogenetic divergence between Batoidei and Selachoidei, and was largely associated with the increased distance between the mouth and first gill slit in Batoidei. Thus the pseudohyoid elements were necessary for providing a support for the hyal rays, as well as the anterior wall of the first gill slit. During the enlargement and extension of these pseudohyoid elements, the original ceratohyal in Batoidei has disappeared.

The study of the hyoid arch of Rhinobatidæ, as represented by *Rhinobatus halavi* and *Rhynchobatus djiddensis* from the Red Sea, supports the view of both Krivetski and de Beer. As a matter of fact, both *Rhinobatus halavi* and *Rhynchobatus djiddensis* are transitional forms between Selachoidei and Batoidei (Bridge[4], Regan[5] and Goodrich[6]). It is found that in these two fishes the original ceratohyal, which has completely disappeared in specialized Batoidei, is still persisting in addition to the pseudohyoid. This ceratohyal, which is relatively much reduced, bears the correct relations of a selachoid ceratohyal to the afferent hyoidean artery, being immediately dorsal to it. Also it is still bearing hyal rays. The originally direct connexion between the hyomandibular and ceratohyal of Selachoidei can be traced by the presence of a ligamentous vestige between the hyomandibular and this reduced ceratohyal. Also the afferent pseudobranchial artery, on running forwards from the efferent hyoidean artery, is median to the pseudohyoid, whereas it is lateral to both the hyomandibular cartilage and the reduced ceratohyal.

Thus the pseudohyoid is a structure altogether distinct from the ceratohyal. Accordingly, the peculiar articulation between the ventral pseudohyoid bar and the reduced ceratohyal is a secondary one. It is gained by the depression of the ceratohyal due to the ventral extension of the ventral pseudohyoid bar. That such an extension has taken place is supported by the fact that the more ventral hyal rays are loosely attache to the ventral pseudohyoid bar while the dorsal ray are completely fused with it. It is to be noted als that the amount of depression of the ceratohyal i *Rhinobatus halavi* is relatively greater than that i *Rhynchobatus djiddensis*. This shows that thes transitional forms represent different steps toward the highly specialized Batoidei, where the ceratohy is completely missing. The condition of *Rhinobatu halavi*, possessing a smaller ceratohyal, seems to b somewhat beyond that of *Rhynchobatus djiddensi* towards the more specialized Batoidei. This agree with the conclusion arrived at by Melouk[7] fro embryological considerations.

Epidermal Glands in Centipedes

The epidermis of a centipede is virtually a epithelium of unicellular glands, their secretion bein extruded over the surface of the cuticle[1]. In additio to the general epidermal glands, there are loca groups of much larger glands histologically simila to the generally distributed glands. Their secretion are chemically similar and, furthermore, they hav similar properties to the sclerotin and pro-sclerotin of the cuticle.

Opening on the sternites of Geophilomorphs ar batteries of large columnar gland cells. The secretio from these sternal glands in *Haplophilus subterraneu* is a white mobile fluid when extruded, but it rapidl hardens into an amber-coloured material on ex posure to the air. Attems[2] has described a simila secretion from the sternal glands of *Himantarium gabrielis*. Similar batteries of glands are found i Lithobiomorphs, though they do not appear to hav been described. They open by numerous pores on th inner, morphologically posterior face of the four dista podomeres (femur, tibia, tarsus and metatarsus) o the last two pairs of legs. They may be referre to as the 'telopodal glands'. Like that of the sterna glands their secretion hardens on exposure, formin a material which is amber-coloured when seen in mas but is normally extruded as long sticky fibre resembling silk. This secretion has been noted b Verhoeff[3] and Willem[4], although they both stat incorrectly that the material is extruded from th coxal glands ('glandes filières' of Willem).

Telopodal glands have been examined in severa species of *Lithobius* and in the related genus *Lamycte* Like the general epidermal gland secretions[1], tha of the sternal and telopodal glands colours wit sudan black. It is intensely positive to Millon' reagent and also gives a positive ninhydrin test. Th secretion thus appears to be a lipoid-protein comple or mixture. It is very similar in this respect to th sclerotin and pro-sclerotin of the cuticle, in whic phenolic groups, probably tyrosine residues, ar ewise abundant[1]. The resemblance of the secretion silk recalls Trim's comparison of the protein-itin complex of the insect cuticle with silk[5]. It has een suggested that the lipoid material from the meral epidermal gland cells of centipedes, having een extruded over the surface of the cuticle, under- oes some change which renders its outer surface rd and inert[1]. Since the secretion from the sternal d telopodal glands appears to be a similar substance d possesses the property of spontaneous hardening, is suggestion may receive further support. A milar relation between the general and special gumental gland secretion and the outer layers of e cuticle has been demonstrated in certain rustacea[6,7].

It is hoped to publish a full account of these special-ed glands in centipedes, together with notes as to eir possible function, in the near future.

'Infra-Red' Brooding and the Crooked-Toe Problem in Chicks

LAST season, following the reports that rearing der the bright emitter type of 'infra-red' lamp used an increased incidence in chicks of a crooked-e deformity, we reared several hundred chicks from r own stock on solid floors so that we could study e problem at first hand. Despite the fact that we d everything possible to induce the condition, for ample, varying the height of the lamp above e chicks, damping the litter, and using various ets, we failed to produce a single case of crooked e.

Towards the end of the season, with the co-operation the National Agricultural Advisory Service, we re able to obtain some growing birds from an out-le source, which had been reared under 'infra-red' d which showed the deformity. Although these rds were obtained primarily for X-ray examination, ey were reared to maturity and bred from for perimental purposes.

Chicks, apparently normal on hatching, from the oked-toed parents have been reared along with me of our own chicks under the same 'infra-red' mp, and whereas 100 per cent of the progeny from e crooked-toed parents have developed the de-rmity, our own chicks have remained quite normal. hen second batches of chicks from both sources re reared together, using ordinary electrical heat-g, neither the progeny from the crooked-toed parents r our own stock developed the malformation.

It would therefore appear that this particular type crooked toe is of a hereditary nature, the suscept-ility being inherited by some strains whereas others e resistant. The indication is that the manifestation this type of crooked toe appears in susceptible ains of chicks under the particular environmental conditions provided, possibly by the combination of bright emitter 'infra-red' lamps—or perhaps prolonged exposure to artificial light—with rearing on solid floors.

If this is the case, then it would appear that certain non-susceptible strains of chicks can be reared successfully under luminous 'infra-red' lamps without the risk of crooked toe deformity appearing: and starting with a 'susceptible' strain it should be possible, by selection, to breed for resistance to the development of crooked toes under 'infra-red' rearing.

While cases of crooked toe in chicks have been previously reported, this hereditary relationship to 'infra-red' brooding has not hitherto, so far as we are aware, been described.

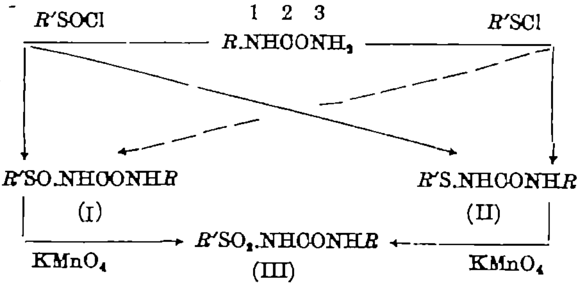
Sulphinylureas and Sulphenylureas

THE interaction of aromatic ureas with carboxylic acid chlorides in pyridine solution under restrained conditions yields N-carbonyl-N'-arylureas[1]. The corresponding reaction with sulphonyl chlorides, however, occurs with simultaneous dehydration and formation of N-arylsulphonyl-N-arylcyanamides[2]. In continuation of the latter work, the action between aromatic ureas and sulphinyl chlorides has been studied. The results obtained necessitated the examination of the corresponding reaction involving sulphenyl chlorides.

Unlike sulphonyl halides, which appear to attack the substituted urea molecule at the oxygen atom (2), forming unstable intermediate O-sulphonylureas $[R\text{NH.C}(:\text{NH}).\text{OSO}_2R']$ [2,3], sulphinyl chlorides substitute at the nitrogen (3), yielding N-arylsulphinyl-N'-arylureas (I) as one of the main products. Considerable quantities of N-arylsulphenyl-N'-arylureas (II), presumably formed by an oxidation-reduction mechanism operating during the reaction, are also isolated. Both products of the reaction are oxidized by alkaline permanganate to sulphonylureas of known formula (III); this observation establishes the structures of the sulphinyl- (I) and sulphenyl-ureas (II); hydrolytic fission of the compounds under various conditions provides further evidence in support of the suggested formulæ. Finally, N-arylsulphenyl-N'-arylureas are found to be almost the exclusive products of the interaction of arylureas and sulphenyl halides.

Thus, for example, the interaction of phenylurea (1 mole) and toluene-*p*-sulphinyl chloride (2·5 moles) in pyridine at 45° for five minutes gave lustrous



plates of N-phenyl-N′-toluene-*p*-sulphinylurea (melting point 164°, decomp.) and opaque needles of N-phenyl-N′-toluene-*p*-sulphenylurea (melting point 172°, decomp.) (each in 25–35 per cent yields), together with smaller quantities of *p*-tolyl toluene-*p*-thiolsulphonate and di-*p*-tolyldisulphide. The analogous reaction with toluene-*p*-sulphenyl chloride gave the sulphenylurea and sulphinylurea in 65 and 3 per cent yields respectively. Similar results were obtained with other members of the urea series.

In their reactions with arylureas, sulphinyl and sulphenyl chlorides thus resemble halides of carboxylic acids rather than those of sulphonic acids. Further experiments in connexion with this work, particularly its extension to the thiourea-series, are in progress, and a detailed account will appear elsewhere in due course.

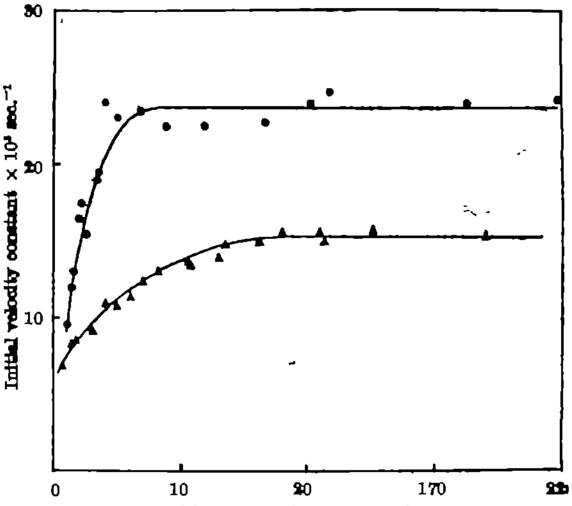
Unimolecular Chlorohydrocarbon Decompositions

THEORIES of gaseous unimolecular reactions have often been discussed[1]; but very few examples of processes occurring virtually completely by this mechanism have been used to compare theory and experiment. Thus the decompositions of azomethane, nitrous oxide and nitrogen pentoxide, which have been exhaustively examined from this point of view, are not now considered to be simple unimolecular reactions[2]. It is desirable, therefore, to have authenticated examples, and some evidence has already been presented that the homogeneous, first-order pyrolyses of ethyl, *iso*propyl and *tert.* butyl chlorides and of ethylidene dichloride are of this type[3]. This evidence is found mainly in comparisons with the obvious radical chain-decompositions of 1.2 dichloroethane and the tetrachloroethanes[4]. In contrast with the latter, the former show no induction periods, no inhibition by propylene, little sensitivity to oxygen and chlorine, and, in the case of ethyl chloride, there is reasonable agreement between the experimental activation energy and that calculated by the semi-empirical method.

These apparently unimolecular processes are now being examined at low pressures in an apparatus essentially similar to that used previously[3,4]. The rate-constants for the decompositions of ethyl chloride and ethylidene dichloride have been shown to fall from the high-pressure values less than $p = 6$ mm. of mercury at 456° C. and 17 mm. at 412° C. respectively. The accompanying graph illustrates the results obtained. It may be noted that at high pressures the reported rate-constants agree satisfactorily with those calculated from the rate-equations given by Barton and Howlett[3].

The classical theory of unimolecular reactions:

$$k = \frac{A\{\exp(-E/RT)\}\,(E/RT)^{s-1}}{(s-1)!}$$



●, Ethyl chloride; ▲, ethylidene dichloride. Note change of scale above 20 mm.

may be used in conjunction with the inflexion poin in the curve of rate-constant against pressure t estimate the number of vibrational degrees of freedom (*s*) contributing towards the activation energy[5]. By assuming collision diameters of 6 A. in eac case[6], the values of *s* are calculated to be 15 fo ethyl chloride and 7 for ethylidene dichloride.

The order of reaction for ethylidene dichlorid pyrolysis begins to rise perceptibly above unity a pressures less than 4 mm. mercury and reache approximately 1·5 at 1 mm. pressure. Thus th evidence that these reactions are truly unimolecula is considerable. Further work is in hand and will b fully reported shortly.

Chlorogenic Acids in Fruit Trees

WORK on the chemical composition of the vario parts of fruit trees, particularly apple and pear, proceeding at Long Ashton and East Malling Researc Stations and the Ditton Laboratory. The proble being studied are not quite the same in each la oratory, but discussions of common interests ha disclosed certain overlapping findings. For th reason, we wish jointly to report the presence of chlorogenic acid in both mature and immature apple and pear fruits, and of this substance and a substance similar to, or identical with, *iso*chlorogenic acid of coffee[1] in leaves and shoots of pear.

Details of the work will be given in independent publications elsewhere.

The Symmetrical Spherical Top

The plastic toy top described by C. M. Braams[1] recalls a similar top described in some detail in Prof. John Perry's "Operatives' Lecture of the British Association Meeting at Leeds, September 6, 1890", or in his book "Spinning Tops", 67–74 (Society for Promoting Christian Knowledge, 1890). He gives the reason for the unusual behaviour of the top in terms of the rule: "Hurry on the procession and the body rises in opposition to gravity", and ascribes the theory of the effect to Lord Kelvin (1874). Perry's Fig. 35, which is on p. 75 of "Spinning Tops", is almost the modern "Tippe Top".

"Library Services in the British Colonial Territories"

The thoughtful and well-informed article on this subject in *Nature* of May 24 will be keenly appreciated by all who also regard the establishment of adequate public library services in these territories as a matter of high priority, being a prerequisite of both economic and social development. The Library Association, with the full co-operation of the Colonial Office, has recently appointed a Committee to advise on all aspects of library provision in the Colonies.

The Library Association warmly supports the contention that "There is clearly a need for a body with driving force capable of providing the finance to establish public libraries and the ability to organize and direct their development until the local governments are able to take over" the responsibility.

Nevertheless, there are difficulties which it would be wrong to under-estimate. First, it is a basic constitutional principle that the Metropolitan Government does not direct Colonial development, or indeed interfere any more than is necessary in local affairs. Thus it is not possible for the British Government to impose any pattern or standards; it can only encourage and guide. Consequently its functions, however implemented, must be limited to initiating and financially aiding pilot or demonstration projects, assisting in schemes for professional education, and affording advice, bibliographical services and the like. Some of this help must be on a short-term basis, preferably diminishing as local support increases. But it is cardinal that initial help should not be withdrawn until the local support is sufficient, otherwise all that has been achieved is thrown away. Yet that is what is in danger of happening, for example, in the Eastern Caribbean. Moreover, all these pilot schemes must enjoy a measure of security, as otherwise planning is impossible, and those who undergo training for librarianship must be assured that they will have permanent scope and employment.

The second great difficulty is that no sound library services can be started or maintained without properly selected, trained and experienced staff. It is, therefore, though obviously unintentionally, misleading to suggest that "the cost of establishing adequate library systems throughout the British Colonial Empire would be very small, and no more than a small team of librarians working in the field would be required". The idea of such a team starting one scheme in one Colony and then moving on to another and so on may seem attractive but is actually impracticable. Each scheme needs two or three first-class, thoroughly experienced leaders capable of starting the job and seeing it through, and of building up well recruited and trained local staff to maintain the services permanently, a task which will occupy a great part of their professional lifetime. We must avoid thinking of library services as inexpensive undertakings. Good libraries must be expensive, which does not prevent their being worth while; on the contrary, the inexpensive are the least worth while. It is absurd to imagine that nation-wide public libraries can, in a year or two and at small cost, be established in the towns and throughout the country districts of a multi-lingual, multi-culture Colony with scarcely any vernacular literature, which will be adequate for the needs of those who can read and those who will be able to read as fundamental education projects begin to achieve full results.

If it is reasonable to argue that any particular Colonial Government cannot afford to maintain adequate libraries, then the case for aid from the British Government is all the stronger. For one thing is absolutely sure: that without education, and the libraries that are the essential accompaniment of educational development, these people will never be able to afford libraries, or anything else beyond bare subsistence. Without adequate library services, the British Colonial territories will never be able to achieve proper standards of living for their peoples, and the ideal of democratic self-government will either remain a dream or prove a tragic failure. Therefore, we would urge all who have a sense of responsibility in this matter to support the Colonial authorities in their educational and library development policies and to urge that the British Council, in co-operation with the Colonial Office, be enabled to resume its library work in these territories, and to resume it with much greater resources than were ever enjoyed before.

Lionel R. McColvin
(President)

The Library Association,
Chaucer House, Malet Place,
London, W.C.1.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturers (Grade B) **in the Department of Chemistry and Applied Chemistry**—The Principal, Royal Technical College, Salford (August 2).

Bacteriologist (with good honours degree and research experience), for work concerned with aspects of the microbiology of the gut flora of the bovine, the pig and the chick used as experimental animals—The Secretary, National Institute for Research in Dairying, Shinfield, Reading (August 2).

Supervising Geologist in the Geological Section of the Department of National Development, Canberra, to be responsible for the supervision of field operations of the Sedimentary Basins Subsection, including geological mapping and assessment of petroleum possibilities of sedimentary basins in Australia, and to prepare reports relating to the occurrence of oil in Australia—The Deputy High Commissioner, Australia House, Strand, London, W.C.2, endorsed 'For the attention of the Senior Representative, Division of Industrial Development' (August 7).

Assistant (with an honours degree in bacteriology, or its equivalent) **to the Advisory Bacteriologist**—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh 8 (August 9).

Demonstrator (with an honours degree in chemistry or biochemistry) **in the Department of Chemistry and Biochemistry**—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (August 9).

Scientist, Grade II (with a good university honours degree, or equivalent, in chemistry or physics, chemical engineering, or fuel technology) on the staff of the Director of Scientific Control at London headquarters—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, endorsed TT/500 (August 9).

Soil Conservation Officers (with a degree in conservation, agriculture, agricultural engineering or pure science)—The Secretary, Southern Rhodesia Government, 429 Strand, London, W.C.2 (August 10).

Assistant Physicist to work on medical applications of radioactive isotopes—The House Governor and Secretary, Royal Cancer Hospital, Fulham Road, London, S.W.3 (August 11).

Assistant Lecturer in Psychology—The Registrar, University College, Hull (August 12).

Director (qualified in archæology or natural history, with experience of the organization of art exhibitions) **of the Art Gallery and Museum**—The Town Clerk, Town Hall, Doncaster (August 14).

Agricultural Economist, and **Assistant Agricultural Economists**—The Registrar, The University, Manchester 13 (August 15).

Lecturer in Chemistry, and a **Lecturer in the Department of Mining and Geology**—The Principal, Wigan and District Mining and Technical College, Wigan (August 15).

Research Officer (with university honours degree, or equivalent qualification) to undertake some fundamental studies into the colloidal properties of a flour-water dough, at the School of Applied Chemistry, N.S.W. University of Technology, Sydney—The Director, Bread Research Institute of Australia, 111 Pacific Highway, North Sydney, Australia (August 15).

Assistant Lecturer in Bacteriology—The Registrar, The University, Manchester 13 (August 18).

Senior Technical Officer in the Coal Research Section, Delhi Road, North Ryde, Australia, to assist in a survey of the physical and chemical properties of Australian coals, with special emphasis on the supervision of staff engaged on the selection and preparation of samples—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2 (August 23).

Leader (with a first- or second-class honours degree in physics or metallurgy, or an equivalent qualification, with at least three years postgraduate research experience) **of the Metal Physics Group** of the Metallurgy Department, Royal Aircraft Establishment, Farnborough—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting A.196/52A (August 29).

Lecturer in Mathematics at University College, Dundee—The Secretary, The University, St. Andrews (September 1).

Lecturer in Physics at New England University College (University of Sydney), Armidale, N.S.W.—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 1).

Lecturer in Plant Physiology in the Department of Botany, Auckland University College (University of New Zealand)—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 8).

Lecturer in Experimental Pharmacology—The Secretary of University Court, The University, Glasgow, W.2 (December 31).

Agricultural Chemist—The Director, Tea Research Institute of Ceylon, Talawakelle, Ceylon.

Assistant (Grade A) to teach **Mathematics** up to Degree standard—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

Assistant Lecturer (Grade B) **in the Physics Department**—The Clerk, Northern Polytechnic, Holloway, London, N.7.

Assistant Lecturer in the Physiology Department—The Warden and Secretary, Royal Free Hospital School of Medicine, Hunter Street, London, W.C.1.

Chemist, to study the degradation of leather in wear, and other related problems—The Director, British Boot, Shoe and Allied Trades Research Association, Satra House, Rockingham Road, Kettering, Northants.

Chemist/Assayer in Northern Rhodesia, to carry out assays and analyses of ores, minerals and rocks in the laboratory of the Geological Survey Department—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. 27106/57/52.

Engineer in the Ministry of Supply near Sevenoaks, to engineer electronic and radar equipment for flying trials—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting D.290/52A.

Engineer with wide experience in the application of electronic and servo-mechanical methods to the control of operations—The Printing, Packaging and Allied Trades Research Association, Patra House, Randalls Road, Leatherhead, Surrey

Experimental Assistant (with a knowledge of chemistry and physics up to degree standard) for research on chalk products—The Director of Research, Research Council of the British Whiting Federation, 245 Ampthill Road, Bedford.

Graduate Assistant Biochemist (experience in hospital biochemistry and a higher degree in chemistry or biochemistry are essential)—The Medical Superintendent Western General Hospital, Edinburgh.

Head of the Department, and a **Plant Breeder**, in the Department of Hop Research—The Registrar, Wye College, Wye, Ashford, Kent.

Head of the Department of Power Engineering and Electrical Technology in the Indian Institute of Science, Bangalore—The Ministry of Labour and National Service (A.S 12), Almack House, 26 King Street, London, S.W.1, quoting A.12/1.30E.

Lecturer in Physiology—The Secretary, Charing Cross Hospital Medical School, 62 Chandos Place, London, W.C.2.

Mechanical and Electrical Engineers in the Works Department of the Air Ministry, in connexion with the design, operation and maintenance of ground mechanical and electrical works services on R.A.F. stations at home and overseas and on Civil Aviation stations—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting D.290/52A.

Physicists and Engineers (Principal Scientific Officer and Senior Scientific Officer grades) at Ministry of Supply London headquarters, for work concerned with the development of guidance and control systems and the application of specialist techniques including radio, radar and electronics to such systems—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting A.206/52A.

Professor of Telecommunication Engineering under the Government of India—The Ministry of Labour and National Service (A.S.12), Almack House, 26 King Street, London, S.W.1, quoting A.12/ITU/193/52.

Soils Chemist or **Physicist** (postgraduate experience is essential), a **Chemical Engineer** for research and advisory work, a **Plant Pathologist** for research on diseases of Hevea, a **Plant Physiologist** or **Biochemist** to study the physiology of latex formation, a **Botanist** to work in Malaya and America on the taxonomy of Hevea, a **Botanist** for preliminary training in the United Kingdom in soil microbiology prior to work in Malaya, a **Chemist** for preliminary training in the United Kingdom in microbiology and bacteriology prior to work in Malaya on rubber latex, and an **Agriculturist** (graduate) for Smallholders' Advisory Service, in the Rubber Research Institute of Malaya, Kuala Lumpur—The Secretary, London Advisory Committee for Rubber Research (Ceylon and Malaya), Imperial Institute, South Kensington, London, S.W.7.

Technical and Research Assistant (honours graduate in oceanography, meteorology, general physics or mathematics) for subjects related to tides—The Director, The Observatory, Birkenhead.

Wool Textile Research Council Fellowships: (*a*) in Organic Chemistry, for work on the chemistry of the wool fibre and allied materials, (*b*) in Physics or Physical Chemistry, for work on the structure of wool and related fibres—The Principal, Technical College, Bradford.

STATE EXPENDITURE ON UNIVERSITIES IN GREAT BRITAIN

THE grant in aid of the universities and colleges in Great Britain, which in the Civil Estimates of 1951–52 amounts to more than £23 million, and which, according to the Chancellor's statement on February 21, is to rise to £25 millions in 1956–57, apart altogether from non-recurrent grants, is by far the largest of the grants in aid of services at home of which detailed accounts are not available to the Comptroller and Auditor-General. No other grant exceeds £200,000, and most of them are less than £20,000. Moreover, any balance issued but not spent by the end of the financial year is not liable to be returned to the Exchequer.

It is generally recognized that certain non-Governmental bodies which derive the main part of their finances should yet, in the public interest, be allowed to retain the maximum degree of independence. Chancellors of the Exchequer and the Treasury itself, no less than the University Grants Committee, have repeatedly emphasized the desirability of preserving the autonomy of the Universities. Nevertheless, the Committee of Public Accounts for 1948–49 expressed the wish to see more effective means of securing adequate Parliamentary control over this large expenditure of public money. Particularly in view of the steep increase in this expenditure in post-war years, it pressed the Treasury to consider whether, without impairing the independence of the universities, any further means could be adopted of informing Parliament more precisely how the grant in aid proposed in the estimate is to be spent and assuring Parliament that grants to the universities are wisely used. The Treasury agreed with this view, and, in a subsequent report from the Committee for the session 1950, it was stated that before arrangements were settled for the next quinquennium, the Treasury would make a very close review in conjunction with the University Grants Committee of what had been achieved. Eventually the Committee of Public Accounts for the session 1950–51 recommended that the books and accounts of bodies which receive the greater part of their income from public funds should normally be open to inspection by the Comptroller and Auditor-General, and this recommendation was welcomed by the Treasury in a Minute dated November 29, 1951.

For reasons which are well explained by Dr. Basil Chubb in his recent book "The Control of Public Expenditure"*, this was as far as the Committee of Public Accounts could pursue the matter. The Select Committee on Estimates, however, is not limited to the examination of the estimates or accounts but is able to pass in review the organization concerned. Its Fifth Report for the session 1951–52† records an examination not so much of university finance as of the functioning of the University Grants Committee and the control it exercises over the expenditure of Treasury grants. The inquiry has been prompted by the considerations already indicated, and it can be said that the University Grants Committee emerges with credit from the scrutiny and that its continued existence is regarded as providing the best solution to the problem of maintaining control.

* The Control of Public Expenditure. Financial Committees of the House of Commons. By Basil Chubb. Pp. viii+291. (Oxford: Clarendon Press; London: Oxford University Press, 1952.) 25s. net.

† Fifth Report from the Select Committee on Estimates, Session 1951–52: The Grant in aid of Universities and Colleges. Pp. 70 (London: H.M.S.O., 1952.) 4s. net.

As this report shows, Treasury grants have now risen from about one-third of university income before the War to two-thirds, and it will be recalled that in a "Note on University Policy and Finance in the Decennium 1947–56" issued in August 1946, the Committee of Vice-Chancellors and Principals concluded that during this decade the pre-war combined annual revenue of the universities would need to be multiplied threefold, and that of this total revenue about three-quarters would have to come from Government sources by way of the University Grants Committee. No fears appear then to have been entertained on the side of the Universities that, with the device of the University Grants Committee, such increased financial reliance on the State need impair their academic independence. On the contrary, this Note stated explicitly: "The Universities entirely accept the view that the Government has not only the right but the duty to satisfy itself that every field of study which in the national interest ought to be cultivated in Great Britain is in fact being adequately cultivated in the University system and that the resources which are placed at the disposal of the Universities are being used with full regard both to efficiency and to economy".

There has in the meantime been no indication of dissent from the view then expressed by the vice-chancellors that the universities may properly be expected not only individually to make proper use of the resources entrusted to them, but also collectively to devise and execute policies calculated to serve the national interest. Both individually and collectively they appear so far to have welcomed an increasing measure of guidance from Government. The main question is as to the form in which that guidance and supervision should be exercised; this question is at the root of the report from the Select Committee on Estimates. Its examination of the functioning of the University Grants Committee is, moreover, of wider interest at the present time, first because of the way in which certain matters such as the expansion of higher technological education affect other bodies besides the universities, with which the University Grants Committee have not even advisory relations, and secondly because of a disposition to suggest the application of a like device in other fields in which State assistance is given.

The University Grants Committee was appointed in 1919: "To inquire into the financial needs of University Education in the United Kingdom, and to advise the Government as to the application of any grants that may be made by Parliament towards meeting them". Although the Committee was merely expected to advise the Treasury on the application of public money granted to the universities of Britain, in practice it has since become also an executive body. The Treasury has left it to th Committee to allocate the money among the universities and to do all the office work in connexion wit this allocation and with the extensive building programme which has proceeded since 1947. Thi position was officially recognized by the Governmen in July 1946, when the terms of reference of th Committee were revised to correspond with th responsibilities which the Committee was actuall discharging. A secondary effect was a substanti reduction of the average age of the members of th Committee by the inclusion of people still engaged i academic work; the Committee now consists of sixtee members, assisted by a staff of twenty-four, an various specialist sub-committees.

Except in one respect, the Select Committee o Estimates makes no criticism of the personnel aspec of the University Grants Committee. Nowhere i this report does it suggest, as was argued in a recen debate in the House of Lords, that the Committee o its staff is obviously overburdened. On the contrary the Estimates Committee was much impressed b the University Grants Committee's close contact wit the universities, the apparent mutual confidenc which exists, largely as a result of the smooth interchange of ideas between the universities and th Committee by frequent informal contact, and th wide understanding of the subject which that Committee displayed. Witnesses were unanimous in thei assurances that consultations always ended in agreement, and that there was no question of the Committe forcing ideas upon unwilling universities.

The Estimates Committee recognizes in this repor the practical efficacy of these frequent and informa meetings which form the basis of the work of th University Grants Committee; but it also gained th impression that much could also depend upon particular personalities, and especially the chairman an the secretary. It comments pointedly on the nee for ensuring continuity in the senior full-time post and particularly on the apparent absence of a arrangement for succession to the post of secretary although the grade of the secretaryship has bee purposely raised to compensate for the absence of full-time deputy chairman. That consideration shoul be given to ensuring continuity in these senior full time posts is one of the five definite recommendations.

It is in the interests of the Chancellor of th Exchequer, the Treasury and the University Grant Committee, on one side, and of the universities, on th other (especially in view of their increased dependenc on public money and the absence of direct Parliamentary control over its expenditure), that eac university should recognize its responsibility to ensur that its affairs are managed with due economy an in the best interests of the nation; and given thi no serious conflict should arise between the tw sides because of the general desire to maintai the independence of the universities and the nee for the exercise of proper financial control bot by the University Grants Committee and b Parliament. That Committee exercises its control i three main ways: through supervision of quin quennial staff requirements, through the receipt of annual returns of staff, students and expenditure, and through the continuous process of unofficial audit by personal contact with the heads and various governing bodies. The last is regarded as the most effective and is manifestly the reason why the Estimates Committee considers the continued existence of the University Grants Committee as providing the best solution to the problem of maintaining control.

The effectiveness of the University Grants Committee lies largely in the fact that the universities are probably best understood by a body consisting mainly of university professors and persons eminent in the academic world acting on behalf of the Treasury. Such a Committee is in a position to suggest the most effective means of meeting new requirements, even if the need for central co-ordination may tend to diminish during a period of consolidation. The confidence entertained in such a body by the universities may be as important a factor as its financial influence in initiating changes and securing new developments; and no factor requires closer consideration than this by those who are considering the adoption of a similar device in other fields of public policy. For here, confidence is based on mutual understanding. Above all, the universities can express their requirements and views to the Committee without the time-consuming necessity of detailed explanations as is often the case where a finance committee is not *au fait* with the problems involved.

Nevertheless, the Estimates Committee does not suggest that the position be left entirely as it is. It recommends the insertion in the Estimates each year of a note reconciling the amount of quinquennial grant proposed for the academic year with the total figure of recurrent grant shown in the Estimates for the financial year. Further, the fullest possible information should be supplied to Parliament, preferably in the estimates, whenever changes in the amount of recurrent grants are made, either as a result of the quinquennial review or at other times, showing the reasons for any change and the basis on which it is calculated. It also recommends that the practice, by which the books and accounts of bodies which receive the greater part of their income from public funds are normally open to inspection by the Comptroller and Auditor-General, should be extended to cover all money advanced by way of non-recurrent grants to the universities for capital development.

The Estimates Committee does not consider that the extension of this practice would in any way encroach on the freedom of the universities, and it will be clear that, having regard to the obligation of the universities to accept the lowest tender, the existing arrangements offer strong safeguards against extravagance already. What seems to be required is not so much closer control as fuller explanation and interpretation of their plans to the ordinary citizen, whether members of Parliament or not, so that the bearing of those plans on the national welfare and particularly the implication of the demands made on the national economy can be clearly understood. This is essential in such matters as the expansion of higher technological education, the organization of scientific and technical research and the problem of earmarked grants for recurrent expenditure. On this last point, the system is regarded, and not only in academic circles, as a serious encroachment on academic freedom. It is strongly disliked in the universities, and in its last report the University Grants Committee, while recognizing that the device was a necessary condition of securing that the developments judged to be desirable in the national interest are rapidly effected, was opposed to its permanent adoption when a satisfactory level of development had been reached in any of the special fields. With this view the Estimates Committee appears to agree in essence. It suggests, however, that when an earmarked grant is discontinued in favour of provision for the recurrent expenditure in the block grant, close scrutiny of the amount involved is desirable and not a mere addition to block grant of the amount of the former earmarked grant. There are occasions, it suggests, when the universities themselves are not in a position to be the best judges of what studies most need to be developed in the national interest. When some important new development needs to be promoted, and the expenditure on this can be isolated from other expenditure, an earmarked grant may afford the best means for keeping Parliament in close touch with the progress of the development.

Concern has been expressed elsewhere that the development of economic and social research in some universities might be impeded if the newer social science departments had to compete for their share of a block grant with the established departments in natural science, for example, instead of continuing to receive the earmarked grant. To that extent, support can be found for the view of the Estimates Committee. In general, however, this report affords no real evidence that the same result in regard to new developments could not be achieved by voluntary agreement or arrangement with the universities. On all that is said in this report it is difficult to imagine the universities refusing to accede to the expressed wishes of the University Grants Committee when based on reasoned argument and in the context of the mutual confidence and continuous informal exchange of views to which this report testifies.

The University Grants Committee thus emerges well from this scrutiny of the Select Committee on Estimates, as indeed it had earlier from that of the Committee of Public Accounts. There is no reason for supposing that the University Grants Committee will fail to take note of the broad hints given in this report as to the desirability of giving both Parliament and the public such further information as will assist in the formation of an intelligent appreciation of what the universities are doing, and a sound public judgment as to the place of the universities in the community and the return that is received from the expenditure of these large sums of public money. The report should dispose, too, of any suggestion that the Committee is over-burdened, or that it could not undertake fresh responsibilities, like that for the supervision of higher technological education.

MORAL PHILOSOPHY AND SOCIAL ANTHROPOLOGY

Experiments in Living

A Study of the Nature and Foundation of Ethics or Morals in the Light of Recent Work in Social Anthropology. By Prof. A. Macbeath. (The Gifford Lectures for 1948–1949 delivered in the University of St. Andrews.) Pp. xii+462. (London: Macmillan and Co., Ltd., 1952.) 30s. net.

PROF. A. MACBEATH has observed that most moralists and writers on ethics "simply ignore the moral judgments of other times and places, and the problems which the differences between the moral judgments of different peoples present for their theories", and realized that our own moral judgments as well as those of other peoples are the result of social conditioning. He is satisfied that there are no fundamental and innate differences between the primitive and the civilized mind, and he sets out to break down the 'iron curtain' between moral philosophy and social anthropology by studying the former in the light shed by the latter.

This purpose is a wholly admirable one, but unfortunately he starts by misstating his premises. He says: "The ways of life of different peoples I regard as experiments at giving concrete embodiment to the formal moral ideal. Each of them is the result of a co-operative effort to work out a way of living which will satisfy the main needs of man". He later qualifies this by saying that the experiments are largely blind; but it is a complete fallacy to suggest that they are experiments at all.

Consider our own code of morals. It is, of course, derived largely from what is known as Christian ethic; but that ethic contains many discrepancies. Let me give an example. In the Ancient East, in accordance with a system which has survived until recent times in Japan, Nepal and Fiji, the kingship was divided into two. There was the war king, whose duty it was to fight against demons, and their human representatives the foreigners, criminals and disturbers of the rites; and above him was the law king, who secured the prosperity of his people by the orderly performance of the rites, and who, since he stood for life, must not come into contact with death in any form. This dualism was taken over by Christianity, and as a result the Christian Church can embrace the soldier, the butcher and the hangman as well as those to whom these trades are abominable. There is a similar discrepancy, also due to ancient religious practices, between the ideals of chastity and of family life. We also have moral notions derived from other sources—the ideals of chivalry acquired by the Crusaders, Greek philosophy as interpreted by the schoolmen, and the Protestant speculations of the Geneva school. All these were foreign, and it was not until the end of the sixteenth century that Englishmen such as Bacon and Hooker began to have ideas of their own on the subject of morals. In spite, however, of more than three centuries of philosophy, there is very little in the moral code of Great Britain that can be supposed to have originated in this country or to have any special reference to the needs and desires of its people. When, therefore, the author quotes with approval the saying of Ross that our rules of conduct "embody the accumulated wisdom of our ancestors", he is propagating a fallacy.

The same applies to the so-called 'primitive' peoples. We know that they have not always lived in a state of isolation, but are where they are as the result of migrations, some of them quite recent. We know that they have all been in contact from time to time with higher cultures, and that there are few primitive areas in which archæologists do not dig up relics of cultures different from, and more advanced than, those now in being. It is true that primitive cultures are functioning wholes, but that is not because they are the result of successful experiments; it is because the odd pieces from various sources of which they are composed have been rubbed or worn down until they fit in together.

Prof. Macbeath supposes that the Australian Blacks have derived their totemic beliefs from their own experience. He might as well suppose that the peasants of Europe have derived their beliefs in the Lamb of God and the Holy Dove from their own experience. These beliefs are, of course, neither totemic nor primitive; but there can be little doubt that they as well as totemism spring from a system of animal symbolism which originated in Asia.

After ably summarizing accounts of the cultures of various primitive peoples, Prof. Macbeath discusses the alleged innate mental inferiority of primitives, and has no difficulty in showing that there is no evidence for such inferiority. In doing so, however, he and his authorities have missed the most important point. He quotes Prof. Lowie as saying that the Crow Indians are not given to systematic thinking. Of course they are not, for systematic thinking is possible only to people who can put their ideas into writing and then arrange them. Illiterates are mentally inferior simply because they are illiterate. It has been held against the African Negroes that they never produced a scientist; but what kind of a scientist would he be who had no weights and measures, no clock or calendar, and no means of recording his observations and experiments? And if it be asked why the Negroes did not invent these things, the answer is that neither did any European people, and for the same reason—namely, that the rare and perhaps unique conditions which made their invention possible were absent. Many learned men seem to fail to realize that if they had not been taught to read and write they would be at best rule-of-thumb craftsmen, the highest skill to which an illiterate can attain.

Prof. Macbeath then sets out to establish "that primitive morality is independent of religion in the sense that the moral ideals of primitive peoples do not derive their goodness, or their moral rules their rightness, from a religious source". Malinowski held that all morality is religious, and the author shows that Malinowski was wrong; but to jump, as Prof. Macbeath does, from the fact that some morality *is* secular to the conclusion that all morality *was* secular is quite illegitimate. He says that "there is a tendency for morality to acquire a religious sanction". This, namely that the secular readily becomes the sacred, is an assumption constantly made by theorists, but nobody has produced a scrap of evidence that it has ever happened; everything that is sacred now was sacred when first heard of. Let us take the example of dancing; if anyone were to maintain that all dancing is religious, it would be easy to show that he was wrong. But there is no doubt that much dancing is religious; and while there is no reason to believe that a secular dance has ever become sacred, there is good reason to believe that all dancing was originally religious. It is easy enough to forget the original purpose of a dance, especially if it has never been written down, and just as easy to forget the origin of a moral rule, especially if it seems natural and obvious, as most of the allegedly secular rules do.

One could go on to show that the differences between civilized and primitive morals are not so great as Prof. Macbeath supposes, and that therefore his refutation of the intuitionist theory neither requires nor receives much support from anthropological data; but it is time to bring this review to a close by expressing regret that so able, accurate and lucid a writer has so often been led astray by those who, whatever their scientific reputation, are careful describers rather than logical thinkers.

SMITHSONIAN METEOROLOGICAL TABLES

Smithsonian Meteorological Tables

Sixth revised edition, prepared by Robert J. List. (Smithsonian Miscellaneous Collections, Vol. 114: Publication 4014.) Pp. xi+527. (Washington, D.C.: Smithsonian Institution, 1951.) n.p.

THE sixth edition of the "Smithsonian Meteorological Tables" reflects the improvements in meteorological practice and the increase in accuracy of measurement of physical constants which have taken place since the publication of the fifth edition in 1931. The new edition contains 174 tables and an index in 527 pages, against 115 tables and index in the 282 pages in the fourth edition. The increase in the number of physical tables is actually greater than 59, because the tables of international codes and symbols used in transmitting and plotting meteorological observations and the list of observing stations have very reasonably been omitted from the new edition.

Since 1931 the advantages of representing the dynamic state of the upper atmosphere by plotting temperatures and heights for fixed pressures rather than the fields of temperature and pressure at fixed heights have been universally recognized, and tables for the construction and use of charts for fixed pressures appear in the new edition. The mass of water vapour in a kilogram of dry air, the humidity mixing ratio, has become for good reasons a much-used measure of atmospheric humidity, and a table, the first to be printed at sufficiently close intervals of pressure and temperature, is given for obtaining it. This table would perhaps have been more useful for British and American meteorologists if the temperature argument had been in Fahrenheit degrees instead of centigrade. Geopotential metres, in accordance with a resolution of the 1947 International Meteorological Organization Conference, replace geodynamic metres. Very detailed information, including a density altitude nomogram and tables of altimeter correction factors, are given for the American (N.A.C.A.) standard atmosphere; this is a little different from the standard used in Europe. It is, however, impossible to enumerate here more than a fraction of the new tables.

An improvement in arrangement is the placing of the explanation of each table immediately before it, instead of placing all the explanations at the beginning of the book. The new arrangement probably requires more space but will save much turning of pages. The explanations and references to sources are fuller and more critical than before. The compilers have decided, for reasons fully stated, to adhere to 980·665 cm. sec.$^{-2}$, adopted in 1892 by the International Commission for Weights and Measures, for the value of g at sea-level at latitude 45° in connecting the absolute unit of pressure with the length of the mercury column and not the more recently determined value 980·62. They naturally use the United States nautical mile, which is 0·2 ft. longer than the British one, with repercussions on the relation of the knot to other measures of velocity. The index is very full; an error noted in it is that the density of mercury is given for p. 3 instead of p. 4.

Meteorologists all over the world will be grateful to the Smithsonian Institution and the United States Weather Bureau, whose staff did most of the work, for producing this new edition of an indispensable work of reference.

G. A. BULL

HYDROGENATION OF OILS AND FATS

Hydrogenation of Fatty Oils

By Prof. H. I. Waterman, with the collaboration of C. Boelhouwer and L. J. Revallier. Pp. ix+254. (New York and Amsterdam: Elsevier Publishing Co., Inc.; London: Cleaver-Hume Press, Ltd., 1951.) 42s.

THIS book, as the author states in his preface, is a review of developments in fatty oil hydrogenation in the light of investigations undertaken during recent years by the author and his collaborators at the Delft Technical University. Prof. H. I. Waterman has produced a stimulating book, which has been translated by Dr. S. Coffey in a competent manner.

As a whole, the book is concise and the subdivisions of chapters is clear and systematic. The appropriate references are conveniently placed at the bottom of the relevant page, and attention is directed to standard treatises; there is a bibliography at the end of the book, together with author and subject indexes. It is not intended to be a complete survey of the subject, and it may seem unbalanced to some readers. This is perhaps understandable, since Prof. Waterman is mainly concerned to show the contribution of himself and his collaborators. Most of the criticisms which may be made against it are on emphasis rather than of substance. Certain sections are treated as an elementary introduction to the fatty oils industry, while in other sections the author would seem to require the reader to have prior knowledge of the subject.

The first part of the book, four chapters comprising a hundred and thirty pages, is a general description of processes utilized in the winning and refining, possibly with a bias towards Dutch practice, of fats, and of the analytical methods used in their technical and fundamental characterization. The section on methods of examination could have been improved by differentiating, on one hand, between those techniques which have become generally accepted by all the leading authorities and, on the other, those not universally favoured.

The remainder of the book is a study of the hydrogenation process. Certain aspects are well done. There is a detailed treatment, in relation to the researches of the Delft school, of the mechanism of hydrogenation, and a critical survey is made of the important subject of selectivity. Adequate attention has been given to methods of representation of the course of hydrogenation of mixed glycerides.

Many readers may be disappointed to find that the technology of fat-hardening is dealt with in seventeen pages and the production of hydrogen, one of the essentials in the process, is inadequately covered in a book with such a title; and no assessment of the principal industrial methods has been attempted.

Despite its limitations there is much to be learnt from this book. The hundred and twenty pages on hydrogenation contain a valuable original approach to the fundamental chemistry of the hydrogenation of oils and fats, and for this reason Prof. Waterman's book will be of interest to advanced students and to chemists and technologists in the fatty oils industries.

H. Jasperson

MINERAL NUTRITION OF PLANTS

Mineral Nutrition of Plants

Edited by Emil Truog. (Published in celebration of the Hundredth Anniversary of the Founding of the University of Wisconsin.) Pp. xiii+469. (Madison: University of Wisconsin Press, 1951.) 6 dollars.

This volume, published under the nominal editorship of Prof. E. Truog, comprises eighteen contributions by different authors, based on papers communicated at a symposium held in the University of Wisconsin. The main object of the symposium was to provide an opportunity for the exposition of the latest views on mineral nutrition, for the mutual benefit of those concerned in the investigation of particular aspects, and for the guidance of those engaged in the practical cultivation of plants, in fertilizer manufacture and in food industries.

Since potential purchasers of a specialist treatise of this type are to some extent influenced by the reputation of the contributors, it is appropriate that these should be indicated in this notice. They are C. E. Kellogg and A. C. Orvedal, E. Truog, C. E. Marshall, R. Overstreet and L. A. Dean, H. Jenny, J. B. Page and G. B. Bodman, A. G. Norman, T. C. Broyer, H. Burström, O. Biddulph, D. Boynton, J. B. Hester, D. I. Arnon, W. F. Loehwing, R. A. Steinberg, R. B. Withrow, C. H. Wadleigh and L. A. Richards, and H. F. Clements. It is at once clear that there assembled at Madison as distinguished a group of mineral nutrition specialists as is likely ever to be gathered together in one place.

The articles are arranged in logical sequence, starting with the soil and the availability of nutrients therein, then passing to the mechanism of entry of mineral nutrients into and their translocation within the plant, leading to the role of minerals and to the disturbances in metabolism resulting from mineral deficiencies. The introductory article, by Kellogg and Orvedal, presents the thesis that, given the proper application of existing knowledge of soil science and the intensification of research where necessary, the extent to which the food-producing capacity of the world can be increased is practically unlimited. Articles of a specialist nature follow, including a particularly lucid discussion by Burström of the mechanism of ion absorption, and a clear exposition by Jenny of the contact theory of mineral uptake. Papers of an applied nature are provided by Boynton and Hester, relating respectively to the cultivation of the apple and of the tomato and other vegetables used in the canning and soup-manufacturing industries. The second of these is of particular interest, not only on account of the array of statistics, such as that the United States tomato crop takes eighteen tons of zinc from the soil annually, but also because of the instance which it provides of the rapid and successful application of academic research results to the commercial cultivation of crops.

There is inevitably a risk of repetition in a composite volume of this type, and in fact the Lundegårdh theory of active ion absorption receives the consideration of three different authors. A good deal of what is contained in the book was already in print elsewhere, adequate references being in most cases provided; but it is undoubtedly advantageous to have all this information, relating as it does to intimately connected but, for administrative reasons, often quite separately pursued fields of inquiry, assembled together within one cover—for the first time, so far as I am aware.

The book will make a very useful addition to the libraries of those concerned with soil science, plant nutrition and cell physiology. This felicitous arrangement whereby the University of Wisconsin marks its own centenary by an act of signal assistance to those engaged in the study of the plant in relation to the soil is in keeping with the well-established traditions of the University.

G. Bond

PSYCHICAL RESEARCH DISSECTED

The Psychology of the Occult

By D. H. Rawcliffe. Pp. iv+551+11 plates. (London: Derricke Ridgway Publishing Co., Ltd., 1952.) 21s. net.

This stimulating and highly provocative book is an attempt to describe and analyse the part "played by various types of psychological anomaly in the creation and perpetuation of occult beliefs and practices". The author has cast his net wide and deals briefly with a large number of subjects ranging from lycanthropy to *PK* (psychokinesis). Following in the tradition of the late Ivor Tuckett (1911), the authors of the famous "Dreimännerbuch" (1925), and more recently Joseph Rinn and Johann Kruse, Mr. Rawcliffe is completely unmoved by the flood of modern propaganda in favour of the reality of so-called psychic phenomena. Even the evidence for mental phenomena such as telepathy and clairvoyance leaves him cold. "There is not even a *prima facie* case," he writes (p. 21), "for the existence of 'psi-phenomena', judged from the scientific standpoint." As for the physical phenomena of the séance room, Mr. Rawcliffe finds the evidence scarcely worth considering. To him the whole of the studies of the psychical research worker are mere examples of magic and superstition dressed up in modern garb and often presented behind a façade of statistical jargon which is intended to disguise the faulty character of the original data.

In support of his position he has skilfully put together a mass of material in which the incompetence and credulity of not a few workers in this field are cruelly displayed. Yet he has omitted much that would have strengthened his case and, it must be added, a good deal that would have weakened it. It is clear that he is of the opinion that an explanation of all parapsychological phenomena is to be sought in facts already known, and that there is no need whatever to invoke anything "psychic", which, in is opinion, implies a return to the mystical, the cult and the supernatural.

In favour of this thesis Mr. Rawcliffe has been at ains to examine a good deal of the literature and as selected a number of instances which illustrate is point of view. Indeed, in one or two cases he is e first to attempt what he calls a "rational" xplanation. Thus he considers endophasic enneurosis nconscious whispering) to be the chief explanation f the majority of the experiments in extra-sensory erception, citing in support of his theory the work f Lehmann and Hansen (1895) and the more recent onclusions in the well-known case of the Latvian easant girl, Ilga Kirps.

It is when Mr. Rawcliffe attempts to deal with the etter class of experiments that his explanations egin to appear somewhat unconvincing. Thus his efutation of the validity of the conclusions drawn y Dr. Soal for some of his work will, I think, scarcely ear expert examination, and his omission of any iscussion of the phenomena of such mediums as). D. Home, Mlle. Tomczyk or Mrs. Piper suggests a ias which is to be regretted.

In spite of its deficiencies, however, this book emains a useful handbook for those who suspect hat much of what passes for psychical research and hich is often unfortunately supported by leading arapsychologists is scarcely worth the paper on hich it is recorded. The book has a useful glossary f technical terms and a selected list of authorities; ut the text contains more than the usual number f printers' errors.

E. J. DINGWALL

BIOLOGY OF HUMAN STARVATION

he Biology of Human Starvation

y Ancel Keys, Josef Brožek, Austin Henschel, Olaf ickelsen, Henry Longstreet Taylor. Vol. 1. Pp. xxii+764. Vol. 2. Pp. viii+765–1386. (Minneaolis: University of Minnesota Press; London: xford University Press, 1950.)

THE physiological effects of a shortage of food occupied the attention of many people during he Second World War, and plans were laid by arious committees in Great Britain to study them nmediately hostilities ceased. In the United States n 1944 Prof. Ancel Keys and his four colleagues ecided to put the matter to the test of experiment. hey received little encouragement from official ources; but, with the financial aid of various eligious and commercial bodies, they launched their reat 'Minnesota Experiment'. Sir Jack Drummond, ho visited Prof. Keys and saw the experiment in rogress, writes that he had rarely come into touch ith an investigation "so meticulously planned and o enthusiastically carried through".

The subjects were young men who had registered s conscientious objectors and who were serving in arious Civilian Public Service Camps. More than a undred volunteered for the experiment; thirty-six ere selected and, of these, thirty-two stayed the ourse. After a control period of twelve weeks, uring which time the men ate an adequate diet and ere subjected to a battery of tests, the period of emi-starvation started. Two meals a day were erved, consisting largely of whole wheat bread, otatoes, cereals, turnips and cabbage. These foods rovided each man with an average of 1,570 calories a day. The semi-starvation period lasted for twenty-four weeks, and by the end of this time the subjects had lost about 25 per cent of their body weights. The photographs at the end of Vol. 2 provide convincing evidence of this. Then followed the twelve weeks of rehabilitation. For this, the men were divided into four groups of eight, each group receiving a different number of calories, varying from 1,930 to 2,940 a day. These calorie groups were further sub-divided so that some of the men in each received supplements of protein or of vitamins. It was soon realized that the allowances of food during this period were too small and they were increased; but it seems likely that, even so, they were not large enough. In any event, when twelve of the men were given the opportunity to eat as much food as they wanted after the official period of rehabilitation had ended, they managed to consume enough food to provide them with 7,000–10,000 calories a day. The whole experiment ended in December 1945.

The investigators had by this time amassed a vast amount of information about the reactions of the bodies and minds of their subjects to a shortage of food, and they were faced with the problem of putting it all together. They decided to make as complete a job of it as they could, and to try to give a comprehensive survey of world knowledge of human starvation in addition to presenting their own findings. The results of their labours are contained in the two large volumes, running to nearly fourteen hundred pages, at present under review. The work of putting all this literature together demands fully as much admiration as the carrying out of the experiment. The morphological, biochemical and physiological effects of starvation are dealt with in the first volume, and the psychological problems are considered in the second, along with special problems such as the relationship of undernutrition to diabetes, neoplastic disease, and to infectious diseases, particularly tuberculosis.

The various results of the Minnesota Experiment take their place among the findings of all the other authors to whose work reference is made. This makes it difficult to visualize the results of the Minnesota Experiment as a whole; but, on the other hand, it is of great value to compare results obtained under experimental conditions with observations made 'in the field' on undernourished populations. The kinds of foods which the subjects ate during the period of semi-starvation were those which the populations of France, Belgium and Holland were forced to live on during the War, and they were the foods which were most readily available in Germany during the period of greatest food shortage in 1946. Prof. Keys and his colleagues conclude that the changes they observed were due first and foremost to a deficiency of calories and not to any specific protein or vitamin deficiencies. This was exactly in accord with the conclusion of workers who had the opportunity of observing the undernourished peoples of Western Europe.

The second volume closes with a list of three thousand references which, the authors write in the introduction, they have consulted in the original. Even if all the authors shared equally in this task, it means that each of them must have read and abstracted at least six hundred papers. Little wonder that they acknowledge "the forbearance of their wives throughout the years of dedication of time and effort to the present work".

E. M. WIDDOWSON

Steroid Hormones and Tumors

Tumorigenic and Antitumorigenic Actions of Steroid Hormones and the Steroid Homeostasis ; Experimental Aspects. By Dr. Alexander Lipschutz. Pp. xi+309. (Baltimore, Md. : Williams and Wilkins Company ; London : Baillière, Tindall and Cox, 1950.) 46*s*. 6*d*. net.

PROLONGED or excessive dosage with œstrogen may lead, in either sex, to hyperplasia or metaplasia of certain tissues. This effect, like other effects of œstrogens, can usually be prevented by the simultaneous administration of progesterone or androgens. Allowing for the large number of gonadally active steroids now available, and for the possibility that certain of the growths induced by œstrogens may ultimately become neoplastic, it will be seen that there is here a prolific field of research.

Among those who have worked in this field, Lipschutz and his colleagues occupy a very prominent place, and their extensive and systematic contributions are summarised in the book under review, especially on experimentally induced fibromata. Lipschutz's thesis is briefly as follows. Production of abnormal growth by œstrogens requires that the stimulus shall be not only prolonged but also continuous. Such continuous œstrogenization can easily be effected experimentally, but in the normal animal is usually prevented by homeostatic mechanisms, notably by the capacity of the liver to inactivate œstrogens. Before any of the œstrogen-induced tumours can be regarded as neoplastic, they must be shown to be autonomous, irreversible and independent of the original stimulus. Unless and until that point is reached, the growth can be inhibited by the simultaneous administration of other steroids which antagonize œstrogens. Lipschutz also directs attention to the fact that to a lesser extent the same thesis applies to androgens. The book ends with a useful discussion of the causes and effects of endogenous hormone imbalance.

Prof. Lipschutz is to be congratulated on having written an informative and stimulating book which will be most useful to those who wish to get a sound grasp of this complicated subject. A. S. Parkes

Physical Chemistry for Schools and Colleges

By H. L. Heys. New edition revised. Pp. 453. (London : George G. Harrap and Co., Ltd., 1952.) 9*s*. 6*d*.

MR. H. L. HEYS'S gift of clear exposition and his avoidance of advanced mathematics have long made this book popular with teachers and particularly suited to the average pupil taking the former Higher School Certificate or equivalent examinations.

To the difficult task of bringing the text into line with such of the present-day theories as can be presented at school-level, and at the same time retaining the simplicity of treatment, Mr. Heys brings a commendable courage and a sound critical judgment. Thus he introduces and justifies the Brönsted–Lowry conception of acids and attempts to apply it ; but he avoids the theory of Lewis. Again, besides discussing the covalent and co-ordinate bonds, he repeatedly shows their relation to chemical behaviour. Besides adding a new chapter in which he has grouped some related phenomena under the heading of "Electrochemical Series", Mr. Heys has extended almost every section, as well as bringing in additional topics such as chromatography, the structure of metals and over-voltage. As a consequence, the size of the book has been increased by 117 pages. The revision has been thoroughly well done, and the book can be strongly recommended.

Les biocatalyseurs

Par Prof. Max-Fernand Jayle. Tome 1 : Enzymes substrats, vitamines et hormones. Pp. 260. (Lons le-Saunier : Impr. M. Declume, 1951.) 950 francs.

THIS is, in fact, the first volume of a treatise on biochemistry, and deals with the biochemical reactions of living organisms and the agents which assist them. (A second volume is announced which deals with clinical biochemistry, especially of blood and urine.) This book can be described as an excellent elementary account which medical students and students of biochemistry and physiology could read with profit. It is up to date in many directions, for example, in giving what is known about the structure of insulin. Some 'anti-vitamins' are mentioned ; but no account is offered of natural antibiotics—possibly because their mode of action is still obscure. The book suffers greatly from a complete absence of references. Many names are mentioned, but nothing to indicate where the student could look for further information.

Atlas of Human Anatomy

By Franz Frohse, Max Brödel and Leon Schlossberg. Explanatory Text by Dr. Jesse Feiring Williams. New edition. Pp. 88. (London : George Allen and Unwin, Ltd., 1952.) 16*s*. net.

THIS new revised edition of the "Atlas of Human Anatomy" reproduces, in pocket size, the Frohse–Brödel wall charts and the Leon Schlossberg's supplementary charts. In addition, there is a short explanatory text by J. F. Williams.

Most of the illustrations are reproduced in colour ; but, in many instances, they have been reduced too much to be of any real value. One or two of the new illustrations, for example, those on pp. 63 and 66, are made very much too large for the details they show. A number of the illustrations, such as the upper figure on p. 55, are confusing. No explanation is given of what structures have been removed.

The text in many places is very vague and often inaccurate ; for example, on p. 20 the following statement is made : "The left ventricle pumps blood *over* the entire body (page 41) except the lungs which are supplied by the action of the right ventricle". Many statements are made which are much too generalized, even for a book of this description.

W. J. Hamilton

The Chemical Technology of Dyeing and Printing

Vol. 2 : Substantive, Basic, Acid and Pigment Colors, Aniline Black, and Dyestuffs for Acetate Rayon and Synthetic Fibers. By Dr. Louis Diserens. Translated and revised from the second German edition by Paul Wengraf and Herman P. Baumann. Pp. xii+446. (New York : Reinhold Publishing Corporation ; London : Chapman and Hall, Ltd., 1951.) 96*s*. net.

THIS is by no means a 'readable' book, though it may be of value to the practical man as a collection of recipes and instructions which appear to be authentic and are certainly specific in detail. The price alone seems likely to limit its sale to those who will find it of practical value in their everyday work. S. M. Neale

NATIONAL PHYSICAL LABORATORY, TEDDINGTON

OPEN DAY

AFTER the extended series of Open Days held at the National Physical Laboratory last year in celebration of the Laboratory's jubilee, the corresponding function this year was confined to a single day, May 23, which was also made the occasion of the annual visitation and meeting of the General Board. In a day of ideal summer weather, nearly one thousand visitors were entertained at the Laboratory. The number of items of research on show was much less than was exhibited last year; but more than one-quarter was concerned with new work.

In the Light Division, a demonstration was given of a development which has recently created considerable interest, namely, transparent electrically conducting films on glass. As a result of methods developed at the Laboratory, it is possible to deposit on glass exceedingly fine films of gold, of the order of a quarter of a millionth of an inch thick, which have an electrical resistance as low as 10 ohms between the opposite sides of a square sample, and an optical transmission as high as about 80 per cent. These results are closely reproducible, so that, although these effects have so far been produced only on small areas of glass, the extension of the idea for the purpose of de-icing aircraft windows and like applications appears to be possible. Also in this Division, further exhibits were shown of recent developments in the manufacture of diffraction gratings by the Merton–N.P.L. process. Gratings so far produced with five thousand lines to the inch are finding a ready application in the field of infrared spectroscopy, where they are replacing costly prisms of such materials as lithium and calcium fluoride in the work of exploring molecular structure.

Several demonstrations were given by the Aerodynamics Division which are of particular importance in the subject of high-speed flight. One of the problems being investigated concerns the effect which may be produced when the boundary layer on a wing or other body moving at high speeds meets a shock wave. In these circumstances it may thicken or separate from the surface, and thus the shape and strength of the shock wave may be modified. Interaction problems of this type are important, and it is essential to understand them in order to allow for the scale effects which result from the use of small-scale models in high-speed wind tunnels. Detailed studies of this type of interaction have been in progress at the Laboratory for several years, and recently a small wind tunnel has been built in which the range of Mach and Reynolds number which can be covered is greater than had been possible previously. The Mach number can be varied from 1½ to 4 by changing the shape of the nozzle used to produce the supersonic flow. The stagnation pressure of the air entering the tunnel can be varied between ¼ and 20 atmospheres absolute, thus giving Reynolds numbers from $0 \cdot 5 \times 10^6$ to 20×10^6 on the flat plate. Results obtained so far indicate that changes of the Mach or Reynolds number have a considerable effect on the interaction. Another section of the work concerns research on delta and arrowhead forms of fighter aircraft. An arrowhead wing was shown in the low-turbulence tunnel, where it was forced to oscillate in pitch by applying a reciprocating force through a spring; movements in the wings were recorded photographically. This work is of importance as this particular type of aircraft, especially when travelling at high speeds, is liable to give rise to undamped pitching oscillations, which make the machine unstable and difficult to control.

The Electricity Division had on show a method for the precise measurement of dielectric constants of pure liquids. These measurements are being carried out in the first instance on benzene, which is being regarded as a standard liquid. The measuring cell consists essentially of electrodes in the form of concentric tubes of platinum fitted with a guard ring, which are mounted in a glass container. Benzene, which is supplied in a highly purified form, is distilled direct into the cell after it has undergone treatment to remove traces of dissolved gases and water. The capacitance of the cell is measured when the dielectric medium is first air (or a vacuum) and then benzene, and the ratio of one capacitance to the other gives the dielectric constant of the benzene. The measurements are being made in the first place at 1,000 c./s. and over a temperature range of 5–30° C. The High Voltage Laboratory has continued work on the measurement of surge voltages, and a divider for use in such measurements was shown. These dividers can be constructed from resistors or capacitors or combinations of both; but, whichever is used, the essential requirement is that the wave-shape of rapidly changing phenomena should be faithfully produced at the oscillograph with a reduction ratio which can be accurately determined. The chief source of error for all forms of divider arises from the earth capacitance of the high-voltage arm; but the effects of inductive residuals in the low- and high-voltage arms cannot be neglected for surges occupying a microsecond or so.

The pilot model of the Automatic Computing Engine which was designed and made in the Electronics Section of the National Physical Laboratory has now been transferred to the Mathematics Division, where it is being used for high-speed computational work. Although the pilot model was originally intended merely as the forerunner of the final machine, it has proved to be particularly useful and will continue to be used while an engineered version and also the final machine are being produced.

In the Metallurgy Division a new method was demonstrated for the preparation of small specimens for tensile tests. In the preparation of specimens of the order of 1/16 in. in diameter, the strain produced in the surface layer by machining is important, although for larger specimens it can usually be ignored. The problem of obtaining small specimens by some other method was solved by making the specimen the anode in a rather unusual electrolytic cell. A jet of suitable solution plays on the blank while it is rapidly rotated and at the same time moved to and fro along its axis at a uniform speed. A current passed between the blank as the anode and a cathode in the jet causes the blank to be dissolved away gradually and uniformly until the desired size is reached. If the current density is high enough and the electrolyte suitable, a truly electropolished surface is produced which is free from irregularities under a high-power microscope, as well as being free from strain. Another exhibit shown by the Metallurgy Division concerned the production of titanium. Although titanium is the fourth most abundant metal in the earth's crust and is widely distributed, it is only since the development of the magnesium-reduction process within the past decade that the metal has shown industrial potentialities. Previously it had not been possible to prepare the metal in a sufficiently pure state, and its true properties are shown only when in this condition. Research is being carried out at the Laboratory on new methods of preparation of the metal and on the constitution of titanium–oxygen and titanium–iron–oxygen alloys. In connexion with research on atomic structure, an X-ray spectrometer capable of dealing with large and small specimens has recently been constructed in the Metallurgy Division. In this instrument, the X-ray intensity is recorded by a Geiger–Müller counter which can be positioned to an angular accuracy of ± 17 seconds of arc. The pulses in the counter are amplified and recorded, and in this way quantitative measurements of diffraction maxima can be achieved in a fraction of the time required to expose and process a photographic plate. To eliminate errors due to variation of the X-ray source, a monitor Geiger–Müller tube is used for measuring the beam incident on the specimen. When the monitor tube has received a predetermined number of counts, it automatically stops the diffraction tube, the count of which thus corresponds to a fixed quantity of X-radiation on the specimen. The overall accuracy attainable is about 0·5 per cent.

Demonstrations were given in the Metrology Division of emitters of highly reproducible waves of light which are being used in connexion with the measurement of distances of up to 0·5 m. to an accuracy corresponding to one-millionth of an inch in ten inches. These sources use pure isotopes either of mercury or of krypton, both of which are now obtainable in sufficient quantity. During recent months, four N.P.L. gauges, the largest being 10 cm. long, have been sent to two other standards laboratories in Europe for measurement in terms of these wave-lengths of light. The results obtained at the three laboratories are in very good agreement, all the measured values for each gauge lying within a range of $\pm 1 \times 10^{-6}$ in. Measurements are also continuing with radio waves 12·5 mm. in length for the purpose of being able to measure up to distances of about 1·6 m. by interferometry. The accuracy so far attained is of the order of 0·0001 in., and the technique which has been developed shows considerable promise of extension to distances of 30 m. or more. A re-determination of the density of mercury is to be carried out in connexion with the National Physical Laboratory standard barometer, and in order to do this a 3½-in. cube of sintered tungsten carbide has been prepared in the Metrology Division workshop with a standard of workmanship which is thought to be unsurpassed. The faces of the cube have been lapped to within 10×10^{-6} in. of flatness, and a little short of this in parallelism, while the edges and corners have also been carefully finished. It is hoped that this perfection of geometric form will permit the volume to be determined from interferometric measurements of the linear dimensions. The cube will then be weighed in air and in mercury in which, by virtue of its density, it will just sink. The accuracy which it is hoped to attain corresponds to better than 0·001 mm. of mercury in the measurement of atmospheric pressure and less than 0·0001° C. in the measurement of temperature at the steam point.

In the Physics Division a new method has been devised for measuring the elastic properties of materials over a temperature-range from near the absolute zero to above red heat. In the new equipment the specimen is lightly suspended in the centre of a long tube and either cooled by surrounding it by cold liquids jacketed in a special form of Dewar flask, or else heated by electrical means. The specimen has attached to it long nickel filaments which can be used for setting it into oscillation and also for measuring the oscillations, since nickel has the property of changing magnetic variations into vibrations and vice versa. The precision obtainable is of the order of 0·03 per cent in favourable circumstances, and thus enables a knowledge of the elastic moduli and of the anelastic behaviour to be obtained. This information is of particular value because of the present tendency for materials, such as turbine blades, to be stressed very highly, even at temperatures in excess of 1,000° C. In another part of the Physics Division, a new Smith bridge has been built for the purpose of measuring normal temperatures to an accuracy of ± 0·0001° C.

In the Ship Division, developments have taken place in the technique for cutting propellers. In the latest method thin steel templates are first cut from an enlarged drawing through a pantograph mechanism, a scale ratio of 5 : 1 being employed. Then the templates are clamped around cylindrical formers in such a way that they give a correct skeleton replica of the face or back of the screw. The formers are mounted on a shaft carrying the screw, and this shaft is rotated and advances so that a follower maintains contact with the template while an electrically driven bandcutter traces the correct section on a metal screw blank. On the final version of the machine it is hoped to cut all four blades at once. A new torsionmeter which had been designed and made in the former Engineering Division workshop was also shown. Although the operating principle is similar to that of the commercial type of instrument, the deflexion is transmitted from one end of the gauge length to the other by means of a small tube lying parallel to the shaft instead of by a shell concentric with it. Thus a very considerable reduction in the size and weight of the instrument has been achieved. The instrument is carried on hardened points bearing on the shaft and is clamped to it by chains ; a range of shaft diameters of 14–22 in. can be accommodated. Experiments are being carried out in the water tunnel on the effect on the cavitation characteristics of a ship's screw arising from a non-uniform velocity distribution of the water. Gauzes of varying mesh inserted in the tunnel circuit are used for producing the appropriate variation in velocity.

In the High Temperature Mechanical Properties Section, an investigation is in progress on the variation of fatigue strength over a speed-range of 10–8,000 cycles per minute on a mild steel for temperatures up to 500° C. It has been found particularly important to investigate the effects resulting from the use of the higher frequencies.

Visitors were also able to inspect the various items of routine test work in the Test House and to discuss problems connected with the maintenance of standards of quality.

VIRUS DISEASES OF FRUIT CROPS

By Dr. A. F. POSNETTE and Dr. R. V. HARRIS

East Malling Research Station, Kent

RECENT developments in the study of virus diseases of fruit crops, with special reference to strawberry and tree-fruits, was the subject of a 'Members' Day' at East Malling Research Station on July 2, when about a hundred visitors were present. The bulk of work on raspberry virus diseases, started in 1920, was transferred in 1942 to the intensive raspberry-growing districts of south-eastern Scotland and continued under the auspices of the Agricultural Research Council and the direction of East Malling; the staff of this investigation was transferred to the newly formed Scottish Horticultural Research Institute in April 1951. The considerable progress made during this period of nine years in our knowledge of the many viruses infecting cultivated *Rubus* species and their complex associations is the subject of a series of research reports at present in course of publication. Work on viruses of blackcurrant and the other *Ribes* species begun in the early 'twenties has recently been resumed at East Malling with the identification of three new viruses, two on blackcurrant and one on gooseberry.

Strawberry Virus Diseases

This work started in 1930 with the distinction of two symptom-types in field plantations, yellow-edge and crinkle. In more recent analytical work, for which Dr. I. W. Prentice was chiefly responsible, these diseases were interpreted in terms of combinations of viruses assigned to three principal groups, (1) mild crinkle, (2) yellow-edge and (3) severe crinkle, on the basis of their differential persistence in the insect vector *Pentatrichopus fragaefolii*. With this advance in the knowledge of the causal viruses, the early grouping of strawberry varieties as virus-tolerant or virus-sensitive is now being superseded by a more exact description of the reaction of each variety to the various viruses and their associations; work on this aspect of the problem is at present seeking a virological interpretation of the loosely called 'break-down' of virus tolerance (in its early sense). This degeneration is a common and disturbing phenomenon in plantations of the leading commercial varieties, Huxley's Giant and Auchincruive Climax. Evidence was recently obtained of a degenerative effect on a clonal race of Huxley, infected only with so-called mild-crinkle virus, when it became infected with a further virus in this low-persistence group. Infection of virus-free Climax plants with the viruses of this group 1 complex, together with group 2 viruses, caused some stunting; but evidence has been obtained recently that another distinct virus is responsible for the severe 'break-down' frequently found in plantations.

Two other diseases, which are prevalent in plantations of the recently introduced Auchincruive Climax variety and are complicating the diagnosis and control of the virus diseases noted above, are being studied. 'Green-petal disease', in which flower and fruit abnormalities are associated with a leaf chlorosis, is thought to be of virus origin, and tests of transmission by grafting and insects are being made. Chloroses similar to descriptions of the 'June yellows' disease in North America are also causing disquiet among growers and propagators of planting stock, and two distinct symptom categories have been distinguished: transient chlorosis of the young leaves in the spring, and a chimæral streaking and speckling which persists throughout the season. The latter form, which has also been observed in varieties other than Climax, is commonly associated with a reduction in vigour. Neither of these forms has so far proved to be transmissible by graft. A third disease, 'sudden yellows', which produces symptoms on Royal Sovereign strawberry easily confused with those of severe yellow-edge, has been shown, however, to be non-virological in origin. Its real cause still remains obscure.

The information from this analysis and evaluation of the viruses concerned in the economic diseases, and from the study of their insect-vector relations, provides the basis for the following studies bearing directly on the problem of control: (1) natural virus ingress and spread in the field plantation, and methods for checking it, and (2) the production and maintenance of planting stocks (runners) free from virus diseases. An approach to the former is being made from four directions, namely, a search for alternative vectors, and for alternative virus-hosts, a determination of the seasonal times of spread of each of the virus components, and, with the Entomology Section, a study of the modification of the pattern of virus spread following the control of insect vectors by means of insecticides. The recent discovery of new aphis vectors was reported in *Nature*[1], and two species of *Potentilla* have been shown to be, in one case a potential, and in the other case an actual, alternative host of strawberry viruses. Time of seasonal spread is being studied by the successive exposure for limited periods of *Fragaria vesca* indicator plants in a plantation of commercial varieties where the viruses are known to be present. The effect of control of vectors by insecticides on the pattern of spread of a virus is being determined from data collected from replicated plots planted with virus-free Royal Sovereign and *F. vesca* plants and subject to complete, partial and nil schedules of spraying with a systemic insecticide.

The selection and maintenance of healthy planting stock, the second objective, is based on transmission tests to indicator species and varieties by grafting and by artificially manipulated insect-vectors, followed by intensive methods for the rapid preliminary multiplication of the selected plants under insect-proof glasshouse conditions.

Finally, experiments on the application of heat-therapy to varieties of which no completely virus-free clones are obtainable have yielded positive results. Thus runners of certain varieties infected with viruses of group 1 and subjected to heat treatment have afterwards failed to induce any detectable symptoms on *F. vesca* indicators. This work is being extended.

Virus Diseases of Tree Fruits

Preliminary observations and experiments on certain suspected virus diseases of apple, pear and cherry were started by Prentice in 1948, and this programme was enlarged and intensified with the arrival of Posnette in 1949. Since then, research has followed two complementary lines: (1) the classification and description of visual symptoms found in orchards, and (2) a critical examination of material thus located by attempted graft-transmissions from trees showing each type of symptom and comparable trees not showing them, to a range of possible indicator varieties and species. In the course of this work an appropriate range of standard indicator hosts for each virus group is being determined, and improved grafting techniques for obtaining quick test results have been devised and put into general use.

The problem as it concerns the scion and rootstock of tree fruits is a dual one, the effect of a rootstock infection being a permanent and growing source of tree infection unless it is eliminated, and that of scion-tree infection more localized and more likely to be eliminated in the normal course of propagation. Also, a combination of stock and scion each infected with different viruses may synthesize complex diseases, which may be disseminated if stocks on which grafts have failed are regrafted or returned to stoolbeds for continued propagation. In this brief survey of present early trends and discoveries, the scion and stock problems will therefore be dealt with separately.

Virus diseases in scion varieties.

Apples. Apple mosaic virus was found to exist in several strains of different virulence, and strains causing extensive leaf chlorosis and defoliation of a variety will probably affect its yield. But varieties differ greatly in their sensitivity to these strains, so that a strain can only be defined as severe in relation to a specified variety, and hence the danger of 'top-grafting' a sensitive on to a tolerant variety. The effects of the rubbery wood virus on a wide range of varieties, additional to the sensitive variety Lord Lambourne, is being determined, following the discovery of the wide distribution of these diseases through infected stoolbeds (see below).

Pear. Besides stony-pit, two diseases of the vein-banding and leaf-flecking type have been identified and appear to have a stunting effect on quince-seedling indicator plants. The possible importance of these viruses in stock-scion incompatibility phenomena is being studied.

Cherry. Four groups of symptoms have been identified and are being studied by graft transmission to a range of species and varieties: rasp leaf, tatter leaf, rosette and rusty mottle. The three latter have reduced the vigour of a clonal rootstock (*F*12/1) by about 20 per cent (girth and height) in two years. Rasp leaf is a more severe disease in its effects, not on *F*12/1, but on most commercial varieties. As its occurrence is comparatively rare, total loss from rasp leaf is probably much less than that from more commonly distributed viruses such as rusty mottle.

Plum. The common vein-banding or line pattern leaf symptoms in plum are probably caused by several viruses. In general, plums are more tolerant to virus diseases than are cherries, and viruses from almost symptomless plums have been found to cause severe leaf-necrosis on cherry. Two recently discovered symptom types on plum, a leaf roll and a bark splitting, are both potentially serious diseases on certain varieties, particularly the gages.

Virus diseases in root-stocks.

Vegetative races of root-stocks hitherto developed at East Malling without reference to the ingress and subsequent dissemination of viruses are being extensively surveyed, with the following results to date.

Apple root-stocks. Some stools of *M*I and *M*IX at East Malling were found in preliminary tests to be infected, without symptoms, with rubbery wood virus. Other varieties of the Malling series from commercial sources were also found to be extensively infected with this virus, and arrangements are in hand to continue the survey on a wider basis with the aim of re-selecting and developing virus-free clones where necessary.

Quince root-stocks (for pear) are under investigation and some infection has been identified.

Plum root-stocks are mainly symptomless carriers, and preliminary tests have detected a widely distributed virus in common plum and Marianna stock. There is some, but probably less, infection in the Myrobalan *B* and Brompton stocks.

Cherry root-stocks. Some clones of Mazzard selections have been found to be infected with ringspot; but the most important selection, *F*12/1, is mainly free from virus. The latter stock, unlike those of plum, commonly shows symptoms when infected, and beds can then be 'rouged' at sight; *F*12/1 is, in fact, used as an indicator-host in our studies of stone fruit viruses.

Selection of healthy propagating stock and indexing of trials. The first step towards the control of these diseases of tree fruits is their elimination from the material used for propagation. This involves not only the re-selection and raising of virus-free root-stocks, but also the selection and distribution of virus-free scion material. This work has already begun, and a survey, by graft-indexing, of virus diseases in existing trials at this Research Station is being undertaken. Plans are also contemplated for investigating the natural vectors of these diseases.

---

[1] Posnette, A. F., *Nature*, 169, 837 (1952)

EDUCATION AND TRAINING OF METALLURGISTS

THE presidential address by Prof. Hugh O'Neill to the Institution of Metallurgists given on June 26 was concerned, first, with the education of metallurgists and, secondly, the maintenance of a high standard of professional conduct.

Whether the founders of the Institution intended it or not, it is a company showing a strong resemblance to the early craft guilds. The three grades of membership, like the corresponding degrees at the universities, were grades through which every common man could pass. They were not social classes; they were degrees and not castes. Professional qualifications were required in many countries during the Middle Ages before a man could practise as a metallurgist. Thus in 1438 Charles VI of France decided that nobody in any town, village or hamlet in Dauphiné could make iron or steel if his competence had not been officially recognized. The old worker, and those who wished to become workers, were examined by an official assisted by two or three experts, who judged their aptitudes and experience. Just as in the days of the Guilds when the apprentices were not only taught the trade, but also received some general education, so is the Institution interested in the training of its members. It is recorded that a goldsmith's apprentice in 1494 agreed to serve ten years instead of nine, provided that his master would keep him one year at a writing school. Among the goldsmiths, fines were inflicted for failing to have the apprentices taught reading and writing. These craft guilds were friendly societies, concerned with the welfare of the *whole* man. They had their religious observances and their festivities.

There is still an element of dissatisfaction, which university teachers themselves share, with the training at present given to many students of metallurgy. Someone wrote to me to say that after interviewing several hundred science graduates he concluded that in all the British universities insufficient attention is directed to the underlying science and philosophy of the subject. He believed that teaching in the history and philosophy of science, plus an account of scientific method, with further philosophical teaching on the nature of truth, are essential ingredients in the training of any man of science who wishes to describe himself as well educated. A further criticism of current training is that: "The educated scientist knows that his science is derived only from a part of experience, and that it does not, and cannot, concern itself with the most important aspects of human life. The universities are to blame. They were instituted to give an education, but to their science students they give little more than technical training. They are, in general, expending far less effort in making wise men and good citizens, than in turning out good employees for commerce and industry. This can be remedied in part at least by insistence that the study of the nature of science should be a necessary part of the training of scientists, and should enter into every final examination".

Exactly one hundred years ago there was penned in Birmingham a famous discourse entitled "Knowledge Viewed in Relation to Professional Skill". John Henry Newman was outlining his ideas about universities, and advocating "liberal education" combined with specialist studies as a definite means of "cultivating the intellect". According to Newman ". . . the man who has learned to think and to reason and to compare and to discriminate and to analyse, who has refined his taste and formed his judgement, and sharpened his mental vision, will not indeed at once be . . . an engineer, or a chemist, or a geologist . . . but he will be placed in that state of intellect in which he can take up any one of the sciences . . . with an ease, a grace, a versatility, and a success, to which another is a stranger".

Some writers would claim that science itself is an adequate basis for the life of a university or nation, especially because of its sociological developments. I must, however, mention a hilarious essay written in this connexion by a serious scientist, which ends thus: "We can, and should, laugh out loud at scientists and this will be the very best way to prevent them from regulating us, or averaging us, or conditioning us to synthetic happiness. For what are they doing? The most laughable thing in the world. They are all crowding round and bowing low before a Sacred Cow". Without being cynical about science we need not become worshippers. In the last century it avoided metaphysics, whereas to-day we have Schrödinger stating: "I consider science an integrating part of our endeavour to answer the one great philosophical question which embraces all others, the one that Plotinus expressed by his brief—*who are we?*, and more than that; I consider this not only one of the tasks, but *the* task of science, the only one that really counts". Sir Walter Moberly, in discussing how the universities should attempt to implant a wide culture, has recommended a limit to religious neutrality, and an active probing of the common values which are held by most men.

It is generally agreed that intense specialization at the undergraduate stage should be avoided. In the words of Prof. Woodward, no one should receive an honours degree without showing "that minimum of general understanding which differentiates education from technical skill". Fortunately in Britain, with its independent universities, we have largely avoided what an American professor has sadly described as the assembly-line technique: "The *part* affixed in this industrial process is the *course*. . . . The course is a neat unit of knowledge, complete in itself, duly fastened to the student's mind, inspected, passed—forgotten. Once it is on, it is on, and we do not have to worry about it any more. When a student has had all the courses bolted on, we look him over to see that nothing has been forgotten, we add up the credits that the courses are worth, and if what we find agrees with the specifications . . . we give him a degree which signifies that he has a college education". The dilemma arises, however, in connexion with the distribution of time for all the work to be done. Some will take the view that the life of Britain depends upon the discovery, development and export of high-quality specialities. For this first-class men of science are required. It still seems to me, however, that we should maintain the broad basis for the bachelor's degree, and intensify specialization in postgraduate work.

The question may be asked: is there such a thing as 'cultural metallurgy'? Prof. John Read recently developed an earlier opinion that "Chemistry itself may become a cultural and humanistic instrument of high value". To that may be added the following statement of Lord Waverley (formerly Sir John Anderson) in his 1951 May Lecture to the Institute of Metals: "I wish it could be universally recognized that scientific studies no less than the humanities have a cultural value, and that applied science is not inferior academically to pure science". For metallurgy to have any humanistic qualities it would probably have to include the history of the subject, and this indeed was the main point of Read's lecture.

How are we to set up and maintain a high standard of professional conduct? This is a moral matter, and increasingly one hears the expression that there is no morality or culture without religion. If we pursue the analogy with the craft guilds mentioned earlier, we find a general understanding that guild conduct should be based on definite religious principles. There would, of course, be hostility from some quarters at attempts to bring Christian principles directly into the sphere of professional conduct, but one cannot help noticing that at a meeting of the representatives of British, French, German and Italian steel industries at Caux, the great need for absolute moral standards in industry was emphasized. There is, however, another direction in which metallurgists in high positions may have to take a definite line regarding their professional conduct. In the development of primitive regions metallurgists should use their influence to see that the conduct of the enterprise corresponds with the natural rights of mankind.

I would conclude by a quotation from a letter signed by "A Professor", presumably American, on "What do we in the Universities believe?":

". . . Underneath our devotion to the fictitious reality, which the physicist at the Einstein level has destroyed, lies sleeping a faith in the existence of a moral universe; in the existence of a natural law which gives to man certain inalienable rights; in a Divine Creator of which we are each a tiny spark. . . . But we are scarcely aware of these foundations far beneath our everyday lives. . . . Only when man-made laws challenge man's inalienable rights do we realise whence comes our belief in these rights".

F. C. THOMPSON

OBITUARIES

Sir Lindsay Scott, K.C.B.

SIR LINDSAY SCOTT, who died on June 17, was an outstanding example of the finest tradition of the amateur in the field of humane studies. A Civil servant fulfilling the exacting duties of a senior official in a war department in peace-time and during hostilities, he nevertheless made a notable place for himself in British archæological research by his resolute determination to match his work against nothing less than that of the highest professional standards in the field or in the museum and library. With a naturally vigorous and original mind, sharpened and disciplined by academic training, he brought to his studies of British prehistory a freshness and directness of approach which was always well ballasted by precise and detailed documentation, and illuminated by direct personal experience. He was, in the eighteenth-century sense of the word, a 'curious' person: his reading was wide and unconventional, and in particular his knowledge of the byways of English literature from its beginnings to the nineteenth century was as varied and unexpected as it was entertaining to his friends, and to this he added a robust and competent command of the practical skills of the countryman and the sailor.

His work was specifically directed to problems of Scottish prehistory, and his main excavations were carried out in the Outer Isles, where perhaps he felt most at home; but these local studies were invariably made within the framework of European prehistory as a whole, and he carried on an amused, but none the less sincere, campaign against provincialism and isolation in such researches. Always provocative (sometimes deliberately and healthily so), his contributions to the archæology of Scotland, both in the form of excavations admirably carried out and meticulously recorded, and in subsequent comment upon the wider aspects of the problems involved, will remain as a permanent memorial to his immense energy and to his devotion to exacting standards of scholarship. These, and his work on the Council for British Archæology and as president of the Prehistoric Society, have ensured him a place among the more powerful forces in the post-war development of prehistoric studies in Great Britain.

STUART PIGGOTT

Mr. F. W. H. Migeod

FREDERICK WILLIAM HUGH MIGEOD was born on August 9, 1872, in Chislehurst, Kent, and went to school in Folkestone. When he was seventeen he joined the pay department of the Royal Navy, and although he had a love for the sea and an interest in those who serve in ships, he was not destined to devote his life to it. After nine years he left the Navy and in 1900 he joined the Colonial Civil Service. All his subsequent service was in Africa, and most of it in West Africa, though he made several important and hazardous journeys across the continent. His curiosity concerning the languages and customs of the various races was insatiable, and his researches resulted in five volumes on languages and four quite considerable travel books. Wherever he went he observed closely, and he amassed a store of natural history knowledge that he used in later writings.

In 1925, when the British Museum East Africa Expedition was left leaderless through the death of W. E. Cutler, Migeod volunteered from England for the post, and intermittently for the next four years or so he acted as general overseer of the operations. On the whole, he had little success in this, and it is paradoxical that through the nature of the work he came into the public eye much more than he ever did through his able and successful studies in folk-lore and language. It is only fair to say that Migeod in these later years did not claim much for his East African adventure.

Migeod's years of retirement in Worthing were characteristically busy. He wrote a book, "Earliest Man", and another volume, "Aspects of Evolution", which displayed a rather fundamentalist point of view; but also revealed a surprising range of observation and width of knowledge of the literature. He also wrote a survey of Worthing.

Migeod was a Fellow of the Royal Geographical and the Royal Anthropological Societies for many years. He had been president of the Worthing Archæological Society in 1927 and he was re-elected in 1938. He also entered local government as a town councillor, eventually becoming an alderman both of Worthing and of the County of Sussex. He was for many years chairman of the local sea-cadet force.

His manner of speech and bearing sometimes gave an impression of arrogance; but in fact he was a kindly and friendly man and an admirable host. Fortune seldom shone on him. His married life was happy but brief, and his wife died many years ago. For the last year or two he had been ill and much alone, and the end came on July 8.

W. E. SWINTON

Prof. Tadeusz Estreicher

PROF. TADEUSZ ESTREICHER (Thaddaeus Estreicher-Rozbierski), a member of an ancient and cultured Polish family and one of Poland's most distinguished and versatile men of science, died in Cracow on April 8. Son of Karol Estreicher, bibliographer and director of the University library, he was born in Cracow on December 19, 1871. He enrolled as a student in the famous Jagiellonian University of Cracow, founded in 1364, where he became a favourite pupil of Karol Olszewski, the celebrated chemist. In 1894, at the request of Sir William Ramsay, Olszewski had begun experiments on the liquefaction of argon; Estreicher participated in this work with distinction, and graduated Ph.D. in 1897. After working in the laboratories of van 't Hoff (Berlin), Ostwald (Leipzig) and Ramsay (London), he returned to Cracow as a *Docent* in inorganic and analytical chemistry; at the same time he helped to modernize Olszewski's laboratory. A further year's work with Abegg (Breslau) was followed by his appointment, in 1906, as professor of inorganic and analytical chemistry at the University of Fribourg, in Switzerland, a chair which he occupied until he was recalled to succeed Olszewski in Cracow in 1919.

Here he was faced with the difficult task of rehabilitating a department which had been devastated during the First World War. In 1923–24 he was dean of the faculty of arts, and in 1926 he was made director of the Pharmaceutical Department in the University of Cracow; his work in the latter capacity resulted, in 1947, in the elevation of this Department to the dignity of a faculty. Meanwhile, at the outbreak of the Second World War, he was doomed to undergo the terrible experience of imprisonment in the concentration camp at Sachsenhausen, following the arrest of himself and many others on November 6, 1939. In this camp a score or so of his colleagues perished, among them his brother Stanislaw, who held a chair in the faculty of law. Although Estreicher survived, he never regained his normal health. When he returned to Cracow upon his liberation the University had ceased to function, and for a time he was obliged to eke out a meagre living as a proof-reader. With the re-opening of the University he resumed his chair; but his health deteriorated so gravely that he soon felt called upon to resign.

Estreicher was vice-president of the Committee of the Polish Pharmacopœia and an active member of the Committee of Pharmaceutical Science of the Polish Academy of Arts and Sciences. He was also a leading organizer of the garden of medicinal plants in Cracow. His researches dealt particularly with the behaviour of gases at very low temperatures. On this theme he published many original papers in German, Polish and British scientific journals. In 1905 he translated into German Travers's well-known work on the experimental study of gases, and in 1915 he published his own book entitled "Kalorimetrie der niedrigen Temperaturen". For the "Polish Biographical Dictionary" he wrote authoritative notices of Kostanecki, Wróblewski and Olszewski, three Polish men of science of the first rank.

First and foremost a chemist, Estreicher was a man of great erudition and varied interests. He was an accomplished classical scholar, a fluent linguist, and a lover of music and the fine arts. Himself an artist of merit, he assembled a fine collection of modern Polish paintings. His writings included essays on the Polish language and literature, and he published also an interesting monograph on the 'Jagiellonian Globe', a valued relic dating from 1510 and preserved in the Jagiellonian Library at Cracow. He cherished a life-long ambition to write a history of Polish chemistry; but although he collected much material and had the ideal equipment for this task he was never able to find time for it. Towards the end of his life he lost both sight and hearing; but as his letters (often dictated in German) testified, he kept to the end his marvellous memory and his clear and alert mind. This remarkable man of science might well have taken for his motto: *Homo sum: humani nihil a me alienum puto.* JOHN READ

NEWS and VIEWS

Electrical Engineering in the Manchester College of Technology: Prof. J. Hollingworth

PROF. JOHN HOLLINGWORTH, who retires from the chair of electrical engineering in the Faculty of Technology in the University of Manchester at the end of August, was educated at Bradfield College, Peterhouse (University of Cambridge), and the Central Technical College (University of London). During the next nine years he was in turn demonstrator at the Central Technical College, lecturer at the College of Technology, Manchester, and held a commission in the Royal Air Force. He was appointed scientific assistant at the National Physical Laboratory, a position which he held for eleven years. During this period he published a number of papers on the propagation of radio waves and allied subjects. In 1932 he was appointed professor of electrical engineering in the College of Technology, Manchester, and under his direction the department has developed in many directions, notably in the teaching of electronics, servo-mechanisms and high-voltage engineering.

Dr. Eric Bradshaw, M.B.E.

DR. ERIC BRADSHAW, who succeeds Prof. Hollingworth on September 1, was born in 1909 and was educated at the King's School, Grantham, and at the Faculty of Technology, University of Manchester, where he graduated in 1930, taking his master's degree a year later. After a course at the works of the British Thomson-Houston Co., Ltd., Rugby, he joined the staff of the Royal Technical College, Glasgow, where he remained until 1944, during which period he took his Ph.D. degree. He was then appointed special lecturer in high-voltage engineering at the College of Technology, Manchester. He is joint author of a number of papers in the fields of high-voltage measurement and electric power-supply. Dr. Bradshaw has served on several committees of the Institution of Electrical Engineers and is now vice-chairman elect of the North-West Centre of the Institution. He has for some years been tutor and lecturer at the Ministry of Education Engineering Summer Schools. He founded and is now editor of the *Bulletin of Electrical Engineering Education*.

Radio-Frequency Allocations in Europe: Conference in Stockholm

THREE of the study groups of the International Radio Consultative Committee met in Stockholm during May 15–27; and these were followed by a European Broadcasting Conference during May 28–June 30. This Conference had been called to consider the assignment of very high frequencies (ultra-short wave-lengths) for sound and television broadcasting in Europe. The work of the Committee was of a technical nature, designed to establish the basis upon which a scheme of frequency-sharing could be devised. For this purpose, one of the study groups presented wave-propagation curves showing the field-strength likely to be obtained from transmitting stations at distances well beyond their normal service area. Another group had studied the discrimination which it is desirable to attain in order to avoid interference between television stations operating in the same frequency-channel. By a combination of these results, the geographical separation desirable between stations sharing the same frequency-band could be established. The Stockholm broadcasting conference has produced an agreement on three plans for the assignment of frequencies to European broadcasting (including television) within the three bands 41–68, 87·5–100 and 174–216 Mc./s. The General Post Office, which is the responsible administration in Great Britain, has stated that the Conference accepted the assignments which the United Kingdom has made for the five high-power and five low-power television stations being established by the B.B.C. For the second band (87·5–100 Mc./s.) the British delegation was successful in securing alternative sets of frequencies for amplitude and for frequency modulation, respectively. The agreement was signed on behalf of the administrations of twenty-one of the thirty-one countries represented at the Conference.

Anatomical Nomenclature

An international meeting of anatomists was recently held in London to discuss a proposal to establish an agreed anatomical nomenclature. The first attempt to reach a similar agreement was the work of a small committee, predominantly German in constitution, which was convened by the German Anatomical Society at its Leipzig meeting in 1887. This committee devised a list of terms, now known as the BNA, which was adopted at a meeting in Basle in 1895. The BNA has been endorsed by a number of countries; but nevertheless is not an internationally approved scheme. In 1933 the Anatomical Society of Great Britain and Ireland approved an English revision, and a German revision was published in 1936. The recent London meeting agreed that any new international nomenclature should be based on the BNA, which it was hoped would require a minimum of change. It was also agreed that each country was at liberty to translate the official Latin terms of the BNA into its own vernacular for teaching purposes; but that, wherever possible, official Latin terms should be used in publications. The revision of the BNA is the responsibility of professional anatomists; but it was decided that it would be in the best interests of all if physiologists, pathologists, clinicians, and others concerned in the education of medical students, should communicate any views they might have about anatomical nomenclature to the committee. According to a recent letter to *The Lancet* (July 5, 1952), Prof. T. B. Johnston (Guy's Hospital, London, S.E.1) is undertaking the task of collating such proposals in Great Britain. The various sub-committees dealing with this matter hope to submit a report to the International Congress of Anatomists to be held in France in 1955.

History of Science

Last year the attention of readers of *Nature* was directed to the publication, by E. Munksgaard, of Copenhagen, of the first two numbers of *Centaurus*, a new quarterly devoted to the history of science and medicine (*Nature*, 167, 841). Three further numbers have since appeared, containing fifteen original articles on a variety of subjects of scientific, medical, biographical and bibliographical interest. Among these may be noted, in Vol. 1, No. 3, a critical article by Prof. Benjamin Farrington on Francis Bacon's "Temporis Partus Masculus", and, in the first number of Vol. 2, Prof. Edward Rosen, of New York, discusses when Galileo made his first telescope. Under the heading "Varia", in Vol. 1, No. 4, is a description of the recently established Belgian Museum for the History of Science, situated in Ghent. First planned in 1939, war delayed its opening until 1948. It was first housed in the Archæological Museum, but latterly was moved to more spacious accommodation in the Museum of Fine Arts. The Museum is stated to be especially rich in old medical and surgical instruments, a new acquisition being a collection of surgical instruments representative of ancient Egypt and the Middle East. Documents, both printed and manuscript, bearing on the history of the sciences also form part of the collections. Each number of *Centaurus* contains several book reviews and there are also extensive lists of books received. The high standard of printing and illustration is maintained, and this quarterly is one well worth the attention of British readers interested in the history of science and medicine.

Gamma-Ray Sources for Radiography

A committee of the Industrial Radiology Group of the Institute of Physics has recently prepared a "Memorandum on Gamma-Ray Sources for Radiography" (obtainable from the Institute; pp. 23; 1952; 3*s*. 6*d*.), which provides a brief statement of the physical characteristics of the gamma-ray sources for radiography by means of which a wide range of radiography can be carried out without X-ray equipment. In addition to the older, costly and somewhat rare, radium there are now available sources consisting of radon obtainable from the Radiochemical Centre, Amersham, and three artificial radioactive sources—cobalt-60, tantalum-182 and iridium-192—from the Atomic Energy Research Establishment, Harwell. Attention is directed in the memorandum to radiographic technique, protection of personnel and precautions to be taken when handling or transporting the sources, and to the cost of installation of the necessary equipment for gamma-radiography. Useful data sheets, summarizing essential information and obtainable from official sources, are included as an appendix to the memorandum. For example, cobalt-60, which has a half-life of 5·3 years and is recommended for the radiography of steel 2–6 in. thick, costs £40 approximately for the equivalent of 1 gm. of radium; the radium can be supplied on loan at a rental of £225 a year. The activity of radium remains sensibly constant with time whereas that of the other sources decreases; but the artificial sources can be returned to the atomic pile for reactivation. With regard to the technique of gamma-radiography, it is mentioned that the technique is simpler than that using X-rays, but the interpretation of the results is a skilled job. Though the radiographer must have an adequate knowledge of protection and must be a responsible person, his training need not be so broad in scope as that for X-radiography, since no high-voltage circuits are involved. Training facilities, though limited, are available in Great Britain, and particulars of these can be obtained from the Institute of Physics, 47 Belgrave Square, London, S.W.1.

Twenty Years of Work at the Jungfraujoch

The November 1951 issue of *L'Astronomie* contains a number of interesting articles, two of which are connected with the scientific station of Jungfraujoch, and are contributed by M. D. Chalonge, director of the station. The first of these refers to the celebration of the twentieth anniversary of the inauguration of the station in 1931, which took place on September 26 and 27, 1951, at Interlaken and afterwards at the Jungfraujoch itself. A short account is given of the various activities of the station in the physics of cosmic rays, astrophysics and the physiology of high altitudes (laboratories have been installed for work in other fields as well). The initiative in the project is due to W. R. Hess, professor of physiology in the University of Zurich, who spent two years in the work of organization, interesting various institutions of other countries in the scheme, and obtaining the necessary financial support to carry it out. Several institutions have combined to endow the station with a small observatory specially well placed for research on spectroscopy and spectrophotometry in the infra-red and ultra-violet regions. The Observatory of Paris and the University of Paris, and also the Observatory of Uccle, have generously presented certain instruments to the station, and the Observatories of Geneva and Basle and the Institute of Astrophysics, Paris, have a scheme for mounting a 40-cm. Cassegrain telescope which will give astronomy an important place at the Jungfraujoch. The second article gives the results of ten years of astronomical observations and refers to the schemes for new research in various fields; it shows the intense keenness of the Director, and everyone will wish him great success in his programme. In concluding the article, he thanks all those who have contributed to the progress of the work, including a group of young students from the Universities of Basle and Zurich, some of whom are now teachers in different places. The list of publications, commencing in 1933, given at the end of the second article, shows the activities of the station and is very creditable to the Director and his staff.

Geography in the Secondary School

At the request of the Executive Committee of the Geographical Association, two of its members have prepared a memorandum on the teaching of geography in secondary schools and, particularly, in modern schools. No young people, they suggest, ought to leave school without the fullest and most understanding picture possible of the locality, the land, and the world in which they will begin to earn their living and live their adult lives. These young people should have some real appreciation of man's dependence in all parts of the world upon the land in which he lives; upon the warmth and moisture without which his crops cannot grow; upon natural resources that he employs to meet his needs, whether simple or complex; upon the essential and irreplaceable few inches of soil which sustain him in his many millions throughout the world. In a world where great distances no longer separate men as they once did, geographical knowledge forms the background essential to an understanding of international affairs and to an appreciation of the differences of outlook which still divide peoples from one another. To help the geography teacher, the writers of the memorandum devote considerable attention to the content and organization of the geography course, the study of geography out of doors, and the use of equipment, including maps. The memorandum has been well conceived and carefully prepared; copies may be obtained from the Geographical Association, c/o the Park Branch Library, Duke Street, Sheffield 2.

Use of Films in the University of Cambridge

The fifth report of the Cambridge University Educational Film Council indicates that, besides regular film sessions in the Department of Geography, weekly sessions of Russian sound films are now provided for students in the Department of Slavonic Studies during all terms. Considerable use is also made of the film for teaching in the Department of Zoology. An interesting development during the year was a further investigation on the use of 'silent' films in education which was carried out in the Department of Engineering. Although more experimental confirmation is required, the evidence provided by this investigation seems to show that, first, when members of an audience have been given the opportunity of comparing 'silent' films shown with and without musical accompaniment, their opinion of what has been the effect of the music on their attention is in general a reliable index of its actual effect, measured by tests made after the showing of the films; secondly, that more students are aided by accompaniment to silent educational films than are hindered; and, thirdly, that those who are aided are those most receptive to the visual film medium. Among the research films which have been made is that of the Cambridge Jotenheim Expedition showing glacier formations, and others on the fur seal of the Pribilof Islands and on the sea-urchin's eggs. The report also contains a complete list of all the films made in connexion with teaching or research at Cambridge.

Current Trends of Physics in the United States

The September issue of the *Journal of Scientific Instruments* (28, No. 9; 1951) contains, in addition to original contributions and other regular features, a special article by Dr. J. C. Overbeck, of the Northwestern University, Evanston, Ill., and is the latest in the series of articles which he has contributed at intervals during the past twelve years on experimental physics in the United States. In his illustrated article, Dr. Overbeck surveys, by selecting several topics from the papers published in American physics journals, the significant trends in the method and technique of experimental physics in the United States during the past two years. The topics chosen include the germanium phototransistor and the germanium rectifier; two new types of mass spectrometer, the one using a time-of-flight method and the other velocity selection; a diaphragm type of pressure gauge for very rapid transient pressures; a novel method of increasing the safe power input of an X-ray tube by twenty to twenty-five times but still retaining the sharp focal spot; photographing sound waves; and an ingenious method of magnifying a crystal layer to provide an image of its atoms. Dr. Overbeck considers the period under review to be one of development rather than of profound new discoveries.

Thirteenth International Horticultural Congress, London

The thirteenth International Horticultural Congress will be held in London during September 8–15 under the auspices of the Royal Horticultural Society. Three general lectures will be given on each of the following subjects: environment, soils and nutrition, plant breeding, and growth and development. In addition, about a hundred and forty lectures will be given at the meetings of the seven specialized sections, which are as follows: fruit growing, vegetable growing, ornamental plant growing, plant breeding, environmental control, seeds, and tropical and subtropical horticulture. The various meetings will be held in the halls of the Royal Horticultural Society, Vincent Square and Greycoat Street, London, S.W.1, and at Church House, Dean's Yard, Westminster, London, S.W.1. Following the week of lectures, there will be tours and day excursions to research stations, gardens, nurseries, fruit- and seed-growing establishments, etc.; visits to places of historical interest will also be included. Other events that will take place during the Congress are as follows. The International Committee for Horticultural Congresses will meet on September 7 and 13; the International Committee on Horticultural Nomenclature and Registration will meet on September 7; a meeting of representatives of botanic gardens under the auspices of the International Botanic Gardens Commission will be held on September 13; and the Flower Show of the Royal Horticultural Society will take place during September 9–10. The membership fee for the Congress is 4 guineas. Further details can be obtained from the Secretary, Thirteenth International Horticultural Congress, Royal Horticultural Society, Vincent Square, London, S.W.1.

The Potsdam Geodetic Institute

FOLLOWING on the political changes in Germany resulting from the War, the Potsdam Geodetic Institute has renewed the publication of its work in a new series of *Veröffentlichungen*, of which six issues have been received, of dates 1949–51. They appear under the auspices of the Deutsche Akademie der Wissenschaften zu Berlin, of which the Geodetic Institute became in 1946 a dependent body, under the directorship of F. Mühlig. The Institute welcomes exchanges of its publications with those of other geodetic workers. The six issues now available deal partly with work begun before the War, as in the study (No. 2, F. Mühlig) of the 24-metre interference comparator, the construction of which was begun in 1937, and in No. 3 (K. Weiken), dealing with pendulum observations, 1934–43. Nos. 1 and 6, by K. Reicheneder, deal with the theory of errors and adjustment of networks in nadir triangulations; No. 4, by H. Haalck, is on gravity-disturbed fields and on the theory of the normal figure of the earth; and No. 5, by the late K. Friedrich and W. Jenne, discusses in much detail the solutions of systems of linear equations in which many coefficients are zero. The back covers of the later issues list some of the post-war publications of the Potsdam Geophysical Institute, prepared by R. Bock, F. Burmeister, F. Errulat, and W. Schumann; they deal entirely with geomagnetism.

Jodrell Bank Annals: A New Astronomical Journal

A NEW publication, to be known as the *Jodrell Bank Annals*, initiates Series 1 of the Astronomical Contributions from the University of Manchester (Vol. 1, No. 1, pp. 1–12; 1952). Through this medium a considerable amount of observational data will be made available to astronomers, especially in connexion with the continuous operation of the meteor, solar and galactic noise equipments at the Jodrell Bank Experimental Station. It is hoped, however, that the *Annals* will also contain, from time to time, contributions to theoretical astronomy from the University and its Mathematical Laboratory. The first publication, "Radio Echo Observations of the Daytime Meteor Streams in 1951", by G. S. Hawkins and Mary Almond, includes a certain amount of material that has previously appeared in *Mon. Not. Roy. Astro. Soc.* and also in *Nature*; but a few new features are worth attention. A new minor stream was detected near υ Piscium on May 12 and 13; but the radiant structure was diffuse. Although it is suggested that this stream may correspond to the Piscid streams observed in 1947 and 1948, the difference of 10° in the right ascension of the radiant renders the identification uncertain. The η Aquarid stream supplied meteors with velocities 63·7, 63·0 and 58·8 km./sec., respectively, as shown in Table 4; but meteors radiating from a radiant at R.A. 336°, Dec. 0°, with a period of Halley's Comet, should have a velocity of 70·4 km./sec. (velocities in all cases are geocentric), and the velocities indicated by the radio echo method correspond to a period of about ten years. This implies that the stream cannot be closely aligned with the orbit of Halley's Comet, nor could it be associated with the October Orionids. Some astronomers doubt very much the connexion of Halley's Comet with either stream—and in particular the Orionids—and hold that the apparent similarity in orbital elements is probably fortuitous. In *Mon. Not. Roy. Astro. Soc.*, 111, 37 (1951), it was shown by Mary Almond that the ζ Perseids and the night-time S. Arietids on October 12, radiant at R.A. 38°, Dec. 12°, were probably associated, and the work of 1951 has reaffirmed the connexion. We can confidently anticipate many interesting items in this new publication.

British Library of Political and Economic Science

THE annual report for 1950–51 of the British Library of Political and Economic Science (pp. 22; London School of Economics, 1951) refers to restrictions on expenditure necessitated by the heavy expenditure of the previous year and the increased cost of books and periodicals, but acquisitions during the year brought the total of bound volumes to 323,575 as against 315,185 in 1950, of which 11,281 were in the lending library and 3,891 in the Shaw library. Expenditure on treatises was £4,187, as against £5,377 in 1949–50, and on periodicals £5,524 as against £3,711; and 6,707 periodicals were currently received as against 6,291 in the previous year. Treatises issued, however, fell from 44,969 to 37,669; but works lent to other libraries increased from 516 to 761, while research readers' permits increased from 452 to 482. Progress has been made with the preparation of the three further volumes of the "London Bibliography of the Social Sciences" which will cover the intake of the Library during 1936–50. A special grant permitted the clearing-off of most of the arrears of binding which had accumulated since the War, but extensions to the fabric had again to be postponed. A list of publications by members of the Library staff is appended.

British Mammals

THE Trustees of the British Museum (Natural History) have again put naturalists in their debt by the production of "A List of British Mammals" (2s. net). This has been written by T. C. S. Morrison-Scott who, after an explanatory account of how the scientific names of animals are devised, describes the use of certain keys to the external characters and skulls of those species which might confuse the layman. Among the mammals described are the hedgehog, mole, seven species of shrew, twelve species of bat, the fox, pine marten and three species of stoat, the weasel, two species of polecat, badger, otter, Scottish wild cat, seven species of deer, three species of hare, the rabbit, two species of dormouse, eighteen species of field mouse, the black and brown rats, the house mouse, twenty-one voles and the coypu. Marine species include the grey and common seals and twenty-three species of whale, dolphin and porpoise. The descriptions are supplemented by a number of clear text-figures.

Medical Research Council Travelling Awards, 1952–53

THE Medical Research Council has announced the following travelling awards for the academic year 1952–53. *Rockefeller Travelling Fellowships in Medicine:* Dr. M. de Burgh Daly, lecturer in physiology, University College, London; Dr. J. E. Hotchin, member of the scientific staff, National Institute for Medical Research, London; Dr. E. L. McDonald, assistant to the professor of medicine, Middlesex Hospital, London; Dr. R. G. Mitchell, lecturer in child health, University of St. Andrews, Dundee; Dr. N. B. Myant, member of the scientific staff, Department of Clinical Research, University College Hospital Medical School, London; Dr. P. C. Reynell, graduate assistant, Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford. *Eli Lilly Travelling Fellowships in Medicine:* Dr. C. J. Earl, junior lecturer, Department of Chemical Pathology, Guy's Hospital Medical School, London; P. H. Schurr, senior registrar in neurosurgery, Radcliffe Infirmary, Oxford; Dr. R. G. White, Freedom research fellow, London Hospital; Dr. G. M. Wilson, senior lecturer in therapeutics, University of Sheffield, and assistant physician, Sheffield Royal Infirmary. *Dorothy Temple Cross Research Travelling Fellowships in Tuberculosis:* Dr. C. N. Iland, lecturer in bacteriology, University of Bristol; H. Platt, University research fellow in veterinary pathology, Department of Pathology, University of Liverpool. *Alexander Pigott Wernher Memorial Travelling Fellowships in Otology:* Dr. D. R. Haynes, Department of Oto-laryngology, Johannesburg General Hospital; Dr. R. F. Naunton, member of the scientific staff, Wernher Research Unit on Deafness, Institute of Laryngology and Otology, Royal National Throat, Nose and Ear Hospital, London. *French Exchange Scholarships in Medical Science* (in association with the Centre National de la Recherche Scientifique): Dr. J. D. Carr, British Empire Cancer Campaign grantee, Poultry Research Centre, Edinburgh; Dr. M. A. Epstein, assistant pathologist (research), Bland Sutton Institute, Middlesex Hospital, London.

Merck Fellowship of the National Research Council, Ottawa

THREE post-doctorate research fellowships, endowed by Merck and Co., Ltd., have been awarded by the National Research Council, Ottawa. The awards, which total 10,500 dollars and travel allowances, with an extra 500 dollars to each institution concerned in order to help pay for specialized equipment, have been made to the following for research as indicated: Dr. S. G. A. Alivisatos (University of Athens and McGill University), enzyme systems, at Bellevue Medical Center, New York City, under Dr. S. Ochoa; Dr. K. K. Carroll (Universities of New Brunswick, Toronto and Western Ontario), factors affecting the hatching of potato eelworms, at the University of Cambridge under Prof. A. R. Todd; and Dr. R. L. Kay (University of Toronto), properties of electrolytic solutions, at the Rockefeller Institute for Medical Research under Dr. D. MacInnes.

"Index of Zoologists"

THE Zoological Section of the International Union of Biological Sciences is engaged on the preparation of an "Index of Zoologists". This will give the addresses, ages and special interests of zoologists throughout the world. The work is well advanced and it is much hoped that it will be published before the International Zoological Congress in July 1953 at Copenhagen. Its completion is, however, delayed by the fact that many zoologists have failed to fill in and return the questionnaire postcard which they received. They are now requested by the Union to complete and return their cards to M. Marc André, 61 rue de Buffon, Paris 5^{e}. If the card has been lost, another can be supplied.

Announcements

THIS year the Australian and New Zealand Association for the Advancement of Science will meet in Sydney during August 20–27. The president will be Sir Douglas Berry Copland, vice-chancellor of the Australian National University at Canberra. The title of his address will be "Authority and Social Control in a Free Society".

MR. COLIN G. CLARK, recently Under-Secretary of State for Labour and Industry and financial adviser to the Treasury, Queensland, has been appointed director of the Institute for Research in Agricultural Economics at Oxford, in succession to Mr. A. W. Ashby, who is retiring under the age-limit provisions.

A DISCUSSION on "Biology as a Career" is being held in Birmingham on October 4 under the auspices of the Institute of Biology. Speakers will include W. P. Yapp, Prof. J. F. Danielli, B. G. Meara, Sir Harold Himsworth, Dr. H. J. Bunker, Dr. W. E. Ripper, G. A. C. Herklots and Sir William Slater. Further information can be obtained from the General Secretary, Institute of Biology, Tavistock House South, Tavistock Square, London, W.C.1.

THE Division of Medicine and Public Health of the Rockefeller Foundation is providing bursaries for postgraduate study and research in public health engineering in universities in the United Kingdom, and for the next three years these will be administered by the Institution of Civil Engineers. Each bursary will be worth approximately £450 and will normally be tenable for one year, and candidates must hold a suitable engineering degree of a university within the British Commonwealth. Application forms (to be completed by August 31) and further information can be obtained from the Secretary of the Institution of Civil Engineers, Great George Street, Westminster, London, S.W.1.

A FELLOWSHIP in any branch of natural science and others in industrial research, virology and agriculture, each worth £A1,000, are being offered by the British Memorial Fund established in Victoria, Australia. The fellowships provide for ten months of study in Victoria and cover all travelling and living expenses during the period. Wives and children are welcomed; but no extra expenses can be paid to cover them. Applicants aged between 25 and 35 and of either sex are eligible, provided they are of British stock with ten years residence in the United Kingdom. Further details can be obtained from Sir John Lienhop, Victoria House, Strand, London, W.C.2, to whom applications should be made immediately.

BIOLOGICAL ACTIVITY OF COMPLEX IONS

By DR. F. P. DWYER and DR. ELEONORA C. GYARFAS
Department of Chemistry, University of Sydney, N.S.W.

AND

DR. W. P. ROGERS and DR. JUDITH H. KOCH
Division of Animal Health and Production, Commonwealth Scientific and Industrial Research Organization, McMaster Laboratory, Sydney, N.S.W.

FOLLOWING the suggestion of Dwyer *et al.*[1], the biological activity of a number of complex ions has been examined. The toxicity of these compounds to mice, their bacteriostatic and bacteriocidal properties and their actions on enzymes have been studied.

Toxicity to mice. The compounds were dissolved in saline and given by intraperitoneal injection. Unless stated otherwise, the results are given in the table as the approximate minimum lethal dose. Owing to the difficulty of obtaining large amounts of the compounds, accurate L.D.50 values were not obtained. The figures are, however, sufficient to indicate the degree of toxicity.

ASYMMETRIC COMPLEX IONS*

Compound	Optical form and toxic dose
Tris-ethylenediamine cobalt III nitrate, $Co(en)_3(NO_3)_3$ (ref. 6)	(+), (−) and (±), 165 mgm./kgm.
Tris-1 : 10-phenanthroline ruthenium II perchlorate, $Ru(phenan)_3(ClO_4)_2$ (ref. 7)	(+), 9·2; (−), > 18·4 mgm./kgm.
Tris-1 : 10-phenanthroline nickel perchlorate, $Ni(phenan)_3(ClO_4)_2$ (ref. 8)	(+), 5·8; (−), > 11·6 mgm./kgm.
Tris-1 : 10-phenanthroline iron II perchlorate (ref. 9)	(±), 14·2 mgm./kgm.†
Tris-2 : 2′-dipyridyl osmium II perchlorate, $Os(dipy)_3(ClO_4)_2$ (ref. 10)	(+) and (−), between 13·5 and 14·8 mgm./kgm.
Tris-2 : 2′-dipyridyl ruthenium II iodide (ref. 11)	(+) and (−), between 15·7 and 16·8 mgm./kgm.
1 : 10-bis(salicylideneamino)-4 : 7-dithiadecane cobalt III iodide, Co(TET)I (ref. 12)	(+) and (−), between 85 and 95 mgm./kgm.
1 : 8-bis(salicylideneamino)-3 : 6-dithiaoctane cobalt III chloride, Co(EEE)Cl (ref. 13)	(+) and (−), between 210 and 220 mgm./kgm.

* (+) and (−) refer to sign of rotation in either the Na_D line or Hg_{5461} line.
† The active forms racemized rapidly at 37° C.

COMPLEX IONS

Compound	Toxic dose
Bis-2 : 2′ : 2″-terpyridylruthenium III perchlorate, $Ru(trpy)_2(ClO_4)_3$ (ref. 14)	> 3 mgm./kgm.
Bis-2 : 2′ : 2″-terpyridylruthenium II iodide, $Ru(trpy)_2I_2$	> 3 mgm./kgm.

NEUTRAL COMPLEXES

Compound	Optical form and toxic dose
Tris-acetylacetane cobalt III*	(±), > 75 mgm./kgm.
Tris-glycine cobalt III	(±), > 150 mgm./kgm.

* First dissolved in alcohol, then diluted with saline

As a rule, with the phenanthroline compounds the addition of the (−) form to the (+) form delayed the time of death slightly. The toxicity of the (+) and (−) forms was approximately additive.

The compounds $Ru(phenan)_3(ClO_4)_2$, $Os(dipy)_3(ClO_4)_2$ and $Ru(trpy)_2I_2$ were given *per os* to mice. The largest doses used, which were five times the toxic intraperitoneal dose, had no effect. The fæces of the mice showed the characteristic colours of the compounds, which appeared to have passed through the alimentary tract unchanged.

Toxic intraperitoneal doses of all of the compounds except the sexadentate chelate compounds, Co(TET)I, Co(EEE)Cl, and the uncharged complexes caused death in 10–15 min. About 1½ min. after dosing, breathing became laboured and then spasmodic. The hind limbs appeared paralysed and then tonicoclonic spasms occurred. Death appeared to be caused by respiratory failure. Atropine potentiated the toxic action of the (+) and (−) forms.

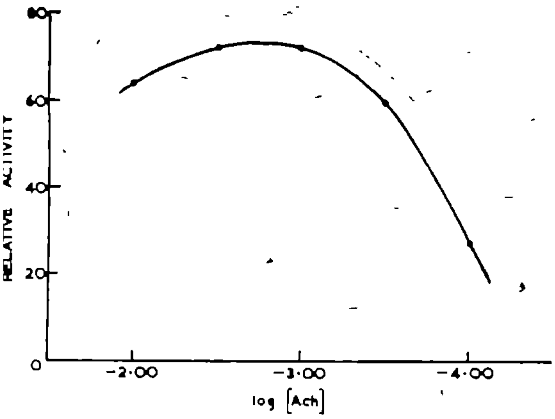
Action on enzymes. The toxic effects of the compounds on the mice suggested that the action of cholinesterase might have been affected, and this enzyme was therefore selected for examination. The enzyme was prepared from the erythrocytes of sheep by a modification of the method of Mendel and Rudney[2]. Activity was estimated manometrically in bicarbonate – carbon dioxide buffer. The compounds were in contact with the enzyme for about fifteen minutes during equilibration; after tipping in the substrate, inhibition was measured over a period of 30 min. It was found that the metal complexes of phenanthroline, dipyridyl and terpyridyl were potent inhibitors of cholinesterase. With a substrate of 0·06 *M* acetylcholine, $Ru(phenan)_3(ClO_4)_2$, 10^{-5} *M*, gave an inhibition of about 80 per cent. The difference between the (−) and (+) forms of the dipyridyl complex was pronounced. At 10^{-4} *M* the (−) form gave about 90 per cent inhibition. The (+) form at the same concentration gave about 20 per cent inhibition; at 10^{-3} *M* the inhibition reached about 75 per cent. The inhibition caused by all of these compounds seemed to be competitive (see graph). No appreciable inhibition was noted with $Co(en)_3(NO_3)_3$.

The use of (±) mixtures of $Ru(phenan)_3(ClO_4)_2$ did not appreciably affect the nature of the inhibition. It appeared that the action of the (−) and (+) forms was additive, and the (+) form did not appreciably antagonize the (−) form.

The action of the complexes on crystalline aldolase prepared by the method of Taylor and Green[3] was examined. Even at high concentrations no inhibition was noted.

Action on bacteria. Concentrated aqueous solutions of the optically active complex salts were sterilized by intermittent heating at 60° C. Appropriate amounts were added to sterile Wright's broth and their effects on the growth of *Escherichia coli*, *Staphylococcus hæmolyticus* and *Salmonella typhi-murium* were examined. With (+), (−) and (±) Co(TET)I, bacteriostatic and sometimes bacteriocidal action at 1/1,000 was noted against *E. coli* and *S. hæmolyticus*. In some instances, the growth of the Gram-positive organisms was inhibited at concentrations of 1/1,000 by (+), (−) and (±) $Ru(phenan)_3(ClO_4)_2$.

Discussion. The neutral complexes examined had no overall charge and had no pronounced biological



ctivity. The complex cations, most of which showed high biological activity, were chemically highly table, co-ordinately saturated, and had no specific ctive groups or centres. The ruthenium and osmium omplexes were not attacked by concentrated acids r alkalis. Dissociation of the complexes could be egarded as extremely small. It may be concluded rom the similarity of the effect in each series of ompounds that the biological activity was a function f the cation as a whole and not of the metallic atom.

From the concept of the "essential neutrality of toms" (Pauling[4]), it may be postulated that the onic charge is not centred in the metallic atoms, but s distributed fractionally over the ligands. The omplex cations thus carried a peripheral charge, hich was related to the total charge, to the electro-ositivity of the metal atom, the electrophyllic roperties of the ligands, and probably to their size. hey thus partake more of the nature of organic ompounds than of simple ions, but differ in that he charge is not localized and is greater in magnitude. Vith the exception of the Ru(trpy)$_2^{++}$ ion, they exist n enantiomeric forms in which the charge distribution eads to non-superimposable mirror-image electrical orms[1].

As a result of the nature of the metal/ligand bonds, harge separation may occur in neutral complexes, hich consequently carry a small peripheral charge[5].

It appears that the inhibition of cholinesterase ccurred by adsorption-electrical interaction on an ctive centre sufficiently close to the ester-splitting entre to inhibit by a steric effect. The absorption entre appeared to be associated with an optically ctive carbon atom which had an asymmetric field ue to the arrangement of four different dipoles. here was thus a general adsorption due largely to e cationic charge; and superimposed, a specific ffect due to differential coupling of the asymmetric elds.

Inhibition by the Ru(trpy)$_2^{++}$ ion, it appears, was ue to the charge alone; but the asymmetry of the elds was important in determining the degree of hibition by the (+) and (−) forms of the tris-: 2′-dipyridyl complexes. It is not clear what ctors influence the magnitude of the specific oupling. However, it is pertinent to point out that robably undue emphasis has been placed hitherto n the purely spatial considerations of optical ntipodes, properties which appear to be incidental o the electrical properties.

The toxicity of the complexes in mice would depend pon the rate of penetration to the site of action and o the specific inhibitory actions at that site. The rate of penetration would depend partly upon the lipid/water partition, and partly upon the nature and configuration of the charge of the complexes. The results suggest that the (+) forms penetrated more rapidly than the (−) forms. The specific action, probably due to the inhibition of cholinesterase in the central nervous system, was also dependent upon the nature and configuration of the charge, (−) forms being more effective than (+) forms.

We are indebted to Mr. G. Merritt, of the McMaster Laboratory, who carried out the bacteriological work, and to the Trustees of the Ian McMaster Bequest for a grant to cover the costs of this investigation.

[March 10.

RADIO OBSERVATIONS OF THE SOLAR ECLIPSES OF SEPTEMBER 1, 1951, AND FEBRUARY 25, 1952

By J.-F. DENISSE
Institut des Hautes Études, Dakar
AND
E. J. BLUM and J.-L. STEINBERG
École Normale Supérieure, Paris, 5e

THE radioastronomy research group working in the Physics Laboratory of the École Normale Supérieure in Paris organized an expedition to observe the annular solar eclipse on September 1, 1951. The totality zone crossed French West Africa and also the Niger near the Markala Dam (lat. 13° 42′ N., long. 6° 04′ W.), which had been chosen as the centre of observation.

The programme consisted of measurements on 9,350 Mc./s. (λ, 3·2 cm.) and 160 Mc./s. (λ, 1·78 m.). The aims were:

(*a*) On the centimetre wave-length: to compare total eclipse measurements made by Hagen, Haddock and Reber[1] in 1950 with annular eclipse observations; such a comparison may prove to be interesting for limb-brightening studies.

(*b*) On the metre wave-length: to study the dimensions of the radio-sun and the brightness distribution across the disk, taking advantage of the present low level of solar activity.

The meteorological conditions were favourable, the local conditions as to interference-level, mains-stability, auxiliary personnel and workshops were excellent and the solar situation was remarkably stable (very few prominences and two sunspots of slight importance).

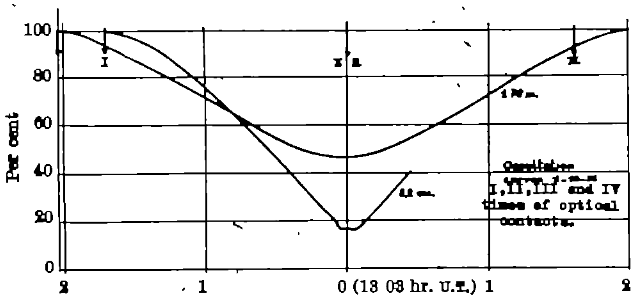

Fig. 1

The results obtained[2] were as follows (Fig. 1):

On the 3·2-cm. wave-length, errors of direction occurred which prevented us from using more than two-thirds of the eclipse duration. We observed that, at the time of eclipse maximum, 16 per cent of the whole radiation remained. This figure may be compared with those obtained by Hagen, Haddock and Reber, namely, 5·6 per cent for an eclipse of magnitude 1·018 against 0·975 in 1951. The disk fraction of area 8·6 per cent which was hidden in 1950 and could be seen in 1951 contributed 10–12 per cent to the total radiation. The theoretical figure is 12 per cent if limb brightening is assumed.

On the other hand, a disk of uniform brightness which would give the same 16 per cent remainder would have a radius of 1·07 that of the sun. The observed occultation curve always lies below the theoretical one computed for a disk of uniform brightness of radius 1·07 that of the sun. This also confirms the existence of limb brightening.

The occultation of a sunspot group is visible on the record. This allows us to see that the 3-cm. emitting area located near this group occupies the same position; its area is certainly smaller than twice the area of the perturbed zone.

On the 1·78-m. wave-length, the occultation curve obtained is the first published on a metre wave-length in a period of solar radio quietness. The relative accuracy achieved is 0·3 per cent. It can be observed that: (*a*) the decrease of the radio radiation begins 16 min. before the first optical contact. The apparent diameter of the radio-sun is 1·35 times larger than the optical apparent diameter; (*b*) at the contact times, 8·5 per cent of the total radiation is occulted; (*c*) at the time of maximum eclips
48 per cent of the total radiation remains.

From these results, we may deduce that th
solar radiation on 1·78 m. wave-length does nc
possess radial symmetry. If we study th
occultation curve for a disk with unifor
brightness distribution with a radius 1·35 tim
that of the sun, we find that 70 per cent
the total radiation must remain at maximu
eclipse. On the other hand, the energy receive
actually decreases much more rapidly ne
optical contacts than for any other model wit
radial symmetry, with uniform brightness
with limb or centre brightening.

The equatorial apparent diameter of the radio-su
on 1·78-m. wave-length is a great deal larger tha
the polar apparent diameter.

These results have been wholly confirmed by th
observation of the eclipse of February 25, 1952,
Marcoussis (near Paris) and Dakar (French We
Africa), where the apparatus used at Markala in 195
is now daily operated. Fig. 2 shows that, at the tim
of optical contacts, a decrease of 0–1 per cent wa
observed in Paris in 1952, 8·5 per cent in Makala i
1951 and 12–13 per cent in Dakar in 1952. Thes
figures confirm the above results. A tentative mod
of the radio-sun observed on a wave-length of 1·78 n
is also given in Fig. 2.

A detailed description of these experiments wi
shortly appear in the *Annales d'Astrophysique*. Th
description of the apparatus will appear in anothe
memoir.

MEASUREMENT AND INTERPRETATION OF EYE-DOMINANCE

By MARGARET M. CLARK
Education Department, University of Glasgow

SUCH expressions as 'the dominant eye' or 'th
master eye' are commonly used; but th
meaning attached to the terms varies considerabl
There is, further, no agreement as to the preci
significance and importance of such a conception
dominance in eyedness. At one extreme are thos
who agree with Gould[1] in believing that righ
handedness follows generally more perfect develop
ment of the right eye; or Parson[2], who stated tha
eyedness is one aspect of dominant sidedness and du
to greater activity of the cerebral hemisphere whic
governs the favoured side. There are also those wh
claim that there is no such thing as a unitary fact
of eye-dominance; that it is only evident under th
artificial conditions of a laboratory experiment, an
even there, probably an artefact.

When one considers what is meant by the actu
term eye-dominance, apart from its real signif

cance, here also there is considerable confusion. By the dominant eye can be meant either the eye with the greater visual acuity, that is, which can actually see better; or the preferred eye, which is not necessarily the same as the former. Matters are still further complicated by the fact that, whereas in handedness most important actions are carried out with one hand only and require a certain amount of skill, resulting in the choice of the same hand at each attempt, in eyedness, on the contrary, the normal method of using the eyes is as 'a pair of structures'. Thus dominance can either be considered when only one eye is being used, or in binocular vision, where in fixating or sighting one eye plays the leading part. All these points have to be borne in mind when constructing tests of eyedness or estimating the significance of such studies, especially where a claim is made that they reveal once and for all the dominant sidedness of the subjects.

In spite of the fact that binocular vision is the normal type, some investigators have used tests to determine the preferred eye for sighting where a deliberate choice of one eye is made. Examples of such tests are: sighting through a narrow tube, looking through a small hole, etc. The type of situation in everyday life when such a choice is made is in shooting with a rifle or using a microscope. Care requires to be taken in such tests to eliminate the effect of the dominant hand on the results. It appears that in instances where a high correlation was obtained between handedness and eyedness this was due to taking inadequate precautions to ensure that the preferred hand did not affect the results. When that precaution is taken, the correlation between handedness and eyedness is low. In early studies of eyedness, visual acuity was sometimes the only measure used. It has since been pointed out by several investigators that comparative visual acuity should not be confused with the dominant eye. Further, it has been shown by Gahagan[3] that in only 55 per cent of his cases was the better eye the preferred one.

It is not evident under normal conditions that one eye is dominant when both appear to be working. Some of the tests designed to determine the dominant eye in binocular vision are such that the subject has both eyes open, and is under the impression that he is using both; but the situation is such that it necessitates the use of only one. Examples of such tests are: sighting through a cone placed over both eyes, or through a small hole in a sheet of paper held at arm's length. If the subject looks directly at the experimenter, then the eye seen through the end of the cone or the hole in the paper is the dominant one. The advantage of using such a test is that the experimenter does not have to rely on the subject's report, which is obviously an advantage, especially in testing children. The use of such a simple technique means also that it has been possible to test children for eyedness at an early age, in fact as early as three years of age; and the eye preference then shown was found to be unchanged at the age of seven. Many more elaborate types of apparatus have been designed to measure eye dominance; but it appears that the simpler methods are as effective. Jasper and Raney[4], for example, utilized the 'phi phenomenon' as the basis for a test, while others have used retinal rivalry as a measure, by employing a stereoscope and presenting a different view to each eye, dominance being determined by the view which is kept longer in consciousness.

A warning which has been given by Crider[5] should be borne in mind. He carried out an investigation to discover the cause of the wide variation in figures found in different studies of eyedness, and claimed that this was due to the different criterion set up by different investigators. Consequently the data of no two investigators are comparable unless the number of sighting opportunities and the criterion are stated, and are in accord. This caution is particularly necessary when considering the figures given for indecisive eyedness.

Crossed laterality is the term used when a person's dominant eye and hand are not on the same side. Many have suggested that the ideal is for these to be in accord, claiming that this facilitates the co-ordination of skilled movements. Starting from the assumption that this is not only the ideal but also the normal, they have explained away cases of crossed laterality as being caused by change of handedness. A consideration of the facts reveals the inadequacy of this explanation. If, as is found, the percentages of right- and left-eyedness are 65 and 35 approximately, while those of handedness are about 94 and 6 respectively, then obviously a considerable number of right-handed people must be left-eyed. In short, the proportion of uncrossed to crossed laterals must be about 2 : 1. It seems absurd in any case to assume that all changed left-handers were left-eyed in the first instance; on the contrary, it would be more feasible to suggest that they may owe their success in making the necessary shift to the fact that they were already right-dominant in one respect, namely, eyedness. A third objection to this view, that crossed laterality results from changed handedness, is the fact that it does not suddenly appear after the children start school, but is also found in pre-school children. To have established that it may be normal to have the dominant hand and eye on opposite sides does not mean that one can dismiss the possibility that it may be advantageous to have them in accord, and that various difficulties may be encountered by those who are right-handed and left-eyed or left-handed and right-eyed. A number of writers have actually suggested that this does bring with it considerable educational difficulties, or even that left-eyedness may itself be an educational handicap. Further investigation is, however, needed on these points. A recent study[6] of the handedness of American top-flight baseball players showed that more than the expected number were left-handed, which leads one to consider the possible findings of an analysis of, say, ace dart players, archers, or crack shots with a rifle, in all of which sports hand–eye co-ordination is so important. It is possible that one would find among them a higher incidence of consistency with regard to hand and eye dominance, that is, more right-handed and right-eyed and left-handed and left-eyed than is found in a random sample of the population. This is an interesting idea, since it is usually said that a person's dominant eye cannot be changed. It would then reveal that the difficulties in learning to fire a rifle may not all be in connexion with handedness; in fact, these may be the least of the trouble. It might be advantageous for a left-eyed person to fire from the left shoulder, while a right-eyed person should fire from the right.

However, to leave the realms of speculation, it appears that dominance of one eye has been established roughly in the proportion of two right-eyed to each one left-eyed, and that it is found in its clearest form in binocular vision—that, in fact, true binocular vision in the sense of identical functioning of the two eyes does not exist. Walls[7] has recently suggested an explanation of eye-dominance by what he termed his theory of directional dominance, claiming that the record of the innervations to the muscles of one eye only are used for the construction of binocular percepts of visual direction. This does not mean that the other eye is unused, but merely implies a differentiation in function of the two eyes. Walls mentioned the fact that after practice the microscopist is able to keep both eyes open without distracting his attention from the slide. If he should, however, attempt to use the other eye, the non-dominant, he will find that the contents of the field of view of the dominant eye are seen superimposed on the instrumental field, and seem to interfere with good observation of the slide. It appears that the benefit of eye-dominance is that it clears the visual field by giving the right of way to the image of one eye, the dominant, making it appear more substantial than the other, which tends to be suppressed.

This survey of the commonest types of eyedness and some interpretation of the phenomenon reveals at least the range of factors considered important by different investigators, and also the necessity for caution in the acceptance of the findings based on such tests. In spite of this, it must be maintained that the dominant eye is a reality, though some of the statements on the subject have been rash, and many of the findings of dubious validity.

RADIATION CHEMISTRY

THE Faraday Society held a general discussion on "Radiation Chemistry" in the University of Leeds during April 8–10. The meetings were well attended and there were many visitors from overseas—forty-four from fourteen different countries—including many well-known workers in this field, among whom was Prof. K. F. Bonhoeffer, president of the Deutsche Bunsen-Gesellschaft für physikalische Chemie. The president of the Society, Sir Charles Goodeve, took the chair on the first day; on subsequent days Profs. C. E. H. Bawn and H. J. Emeléus presided. The authors were allowed five minutes to make the salient points of their contributions, so that ample time was left for discussion.

Radiation chemistry—the study of the chemical effects of photons, electrons, or positive ions of an energy greater than 50 eV.—has made rapid progress during the past few years, mainly owing to our increased knowledge of the chemistry of free radicals and of molecular ions. Its relatively slow development compared with that of photochemistry is due to the greater complexity of the primary process: in photochemical reactions this is simple and involves the absorption of a quantum of radiation by a molecule; but the transfer of energy from short wave-length radiation or from bombarding particles is complex, and prediction of the mechanism or of the products is uncertain. The object of this discussion, the first to be held on the subject by the Faraday Society, was to review the present position, to attempt a synthesis of the differing points of view of physicists, chemists and biologists, and to suggest further lines of development.

The general introduction was given by Prof. F. S. Dainton (Leeds), who reviewed the present difficulties of the subject and directed attention to the more important problems which have to be solved. He emphasized the lack of knowledge of the nature of the primary process; the value of the energy (W) required for the formation of an ion pair (formed along or near the track of the bombarding particle) is not known for liquids, nor how it is related to the ionization potentials of molecules with which the impinging particle collides. The relation of the mean ion density to the energy, mass and atomic number of the particles is, however, known qualitatively at least, and forms the basis of hypotheses which relate the amount and nature of the reaction product with the mass and energy of the particle. Caution must be observed in applying to liquid systems conclusions based on the gaseous phase; but cases are known in which such extrapolations are legitimate. In polar media, however, the magnitudes of solvation energies and entropies are such as to invalidate the assumption of parallel behaviour in the liquid and the vapour, and they refer to equilibrium conditions not relevant in systems in which the charge transfer processes are very rapid. Prof. Dainton directed attention to some important questions which would be discussed at the meeting: the observed value of G_R, the fraction of the absorbed energy used in the formation of radicals, may be a function of the solute and may depend on other competing processes, and thus the maximum observed values are likely to be the more significant; differences in track density leading to variations in ionic yield may arise from quite small changes of energy—a point of considerable importance to radiobiologists; although the initial distribution of primary products is non-uniform, rate expressions based on uniform distribution may successfully account for the observed kinetic behaviour; the radiolysis of water produces species which may lead either to the oxidation or the reduction of certain solutes, and a considerable knowledge of the behaviour of the system under varying conditions is necessary before theoretical conclusions are made; the concept of protection and sensitization in biological systems may be of importance in simpler systems.

The first three papers were on the primary act. Prof. F. W. Spiers (Leeds) reviewed the processes of absorption of ionizing radiations in terms of the quantum energy, and discussed the relative importance of the photoelectric, Compton recoil and the pair-production processes in the absorption coefficient of water. (Data for water for some commonly used radiations were given.) The loss of energy by charged particles was discussed in terms of the stopping power of the medium given by the theory of Bethe and its modifications. The magnitude of the energy (W) required to produce an ion pair was discussed in relation to the type of particle, its speed and the properties of the absorbing medium, and finally some indication was given of the distribution of ion pairs along the track of the fast-moving particle. Prof. H. S. W. Massey (London) dealt with the nature of gaseous ions, and the formation of clusters by alkali metal ions with polar molecules and with rare gas atoms, and described recent work on the molecular ions of the rare gases. He directed attention to certain features of atomic and molecular negative ions and to metastable ionic states. The second part of his paper was concerned with the rates of reactions involving ions, their classification, and the different processes which may occur. Prof. J. L. Magee (Notre Dame) examined the mechanism of charge neutralization in reactions between positive and negative ions by means of potential energy curves and their crossing-points, and gave a theory of the probability of transition. He concluded that the reactants retain their constituent atoms and configurations, and that dissociation may follow, but not rearrangements involving both the ions; highly excited states are to be expected, and radicals should be common reaction products. In the discussion which followed, some consideration was given to the problem of light emission and its role (if any) in radiation chemistry.

The next group of papers were devoted to actinometry. Dr. N. Miller and J. Wilkinson (Edinburgh) compared and criticized a number of systems which have recently been proposed for chemical dosimetry. They discussed the characteristics of suitable reactions in aqueous media, and summarized the pertinent data for the oxidation of ferrous ions in air-saturated 0·8 *N* sulphuric acid solutions, the reduction of ceric ions in similar solutions, and the hydroxylation of benzene in air-saturated water. There is considerable lack of agreement, except for ferrous sulphate solutions at lower dose-rates. The results were presented of their exhaustive tests designed to examine the variables which might cause irreproducibility in this system with X- and with γ-rays. The system is also applicable to electron dosimetry, but not to that of heavy particles. Non-aqueous systems were also discussed. Prof. F. S. Dainton, in his introductory remarks, expressed the gratitude of the meeting to Dr. Miller and Mr. Wilkinson, and hoped that it would be generally agreed to use the aerated ferrous sulphate actinometer for X- and γ-rays with dose-rates less than 1,000 r./min. Prof. Milton Burton (Notre Dame) strongly supported this view, and stressed the desirability of recording the total amount of chemical change per unit of energy absorbed (for example, as the so-called *G*-value or radiation yield per 100 eV.) rather than the ionic yield. J. Wright (Harwell) described experiments on the pile irradiation of various chemical systems, designed so that they could be related to calorimetric measurements, which will ultimately be the basis of dosimetry for pile radiation chemistry. It was found that the ferrous sulphate system was suitable for short irradiations and gave information about the γ-radiation resulting from the decay of fission products. General discussion followed, devoted partly to a consideration of post-irradiation effects in the ferrous sulphate system.

Attention was then directed to the radiolysis of pure liquids. Prof. Burton and S. Gordon (Notre Dame) discussed the use of mass-spectrometric and radiation-chemical data on the same compounds for the interpretation of their mechanism of decomposition; the ions revealed by the former process are complementary to the radicals of the latter. The application of these methods to the radiolysis of benzene and heavy benzene (C_6D_6) shows that decomposition may occur either by bond rupture or by rearrangement; in a mixture the two compounds protect each other against radiation. A. Prevost-Bernas, A. Chapiro, C. Cousin, V. Landler and M. Magat (Paris) reviewed the possibilities and the limitations of two methods they have used for the determination of the number of free radicals formed in organic liquids by ionizing radiations, and gave estimates of the fraction of the energy used in free radical formation. They also discussed the mechanism of the production of free radicals in liquids irradiated in a pile, and the contributions of the different radiations present.

The radiolysis of water is important not only for its own sake but also because it is a factor in the study of the radiation chemistry of aqueous solutions. Dr. A. O. Allen (New York) discussed his mechanism of the decomposition of water, based on the very large amount of experimental work done in his laboratories during the past five years, according to which molecular hydrogen and hydrogen peroxide are formed simultaneously with the production of hydrogen atoms and hydroxyl radicals, the molecular yield increasing, and the radical yield decreasing, with the ionization density of the radiation. The reverse reaction, $H_2 + H_2O_2 \rightarrow 2H_2O$, which is initiated by free radicals, is favoured by dissolved hydrogen and retarded by dissolved oxygen or hydrogen peroxide. The molecular decomposition is ascribed to reactions occurring in very small regions —hot spots. Dr. Allen also discussed the conditions to be satisfied in experiments designed to determine the molecular (G_M) and radical (G_R) radiation yields in water, and gave provisional values for these quantities which were the subject of some discussion. Prof. P. Bonet-Maury (Paris) also discussed the formation of hydrogen peroxide and of hydrogen from pure water by radiations of different types, and the possible secondary reactions and equilibria which may occur.

The next group of papers was on the radiation chemistry of aqueous solutions. Dr. M. Haissinsky (Paris) considered the mechanism in dilute solutions in terms of the oxygenated radiolytic derivatives of water. Oxidation reactions preponderate; but reduction reactions are caused by hydroxyl radicals either directly, or indirectly by reaction with molecular hydrogen to give water and hydrogen atoms. It was suggested that hydrogen is produced chiefly by the process, $H_2O + e = H_2 + O^-$, which leads to the formation of two hydroxyl radicals and one molecule of hydrogen per ion pair. Dr. C. B. Amphlett (Harwell) described experiments in which the oxidation of ferrous ions by X- and γ-radiation was studied in dilute sulphuric acid solutions of different concentrations and in the presence and absence of complexing agents. The variation in the initial oxidation-yield with *p*H suggests that the primary act is more complex than is usually assumed. Values of the 'equivalent redox potential' of irradiated water with respect to the ferrous–ferric system were obtained. Dr. W. M. Garrison and Prof. G. K. Rollefson (Berkeley) described elegant tracer experiments on aqueous solutions containing ferrous ion and carbon-14 dioxide irradiated with high-energy helium atoms, and found that the principal products were ferric ion and hydrogen in the molar ratio two to one; formic acid and much smaller amounts of formaldehyde and oxalate were produced. A mechanism giving a rate law which agrees with the experimental data was proposed.

Papers mainly concerned with the decomposition of hydrogen peroxide followed. Dr. J. Weiss (Newcastle upon Tyne) discussed the photochemical decomposition in relation to that by ionizing radiations, and obtained rate expressions for the reactions occurring within, and between, the tracks. Dr. E. J. Hart and M. S. Matheson (Chicago) described experiments with continuous and intermittent γ-radiation on aqueous hydrogen peroxide solutions in paraffin-coated cells, in which they found that the decomposition yield depended on the square root of the hydrogen peroxide concentration and inversely on the square root of the dosage-rate. A novel feature of the mechanism proposed was that chain termination results from the termolecular reaction $2HO_2 \rightarrow H_2O_2 + O_2$, in which hydrogen peroxide is regarded as being a third body of exceptionally high efficiency. Dr. M. Ebert and J. W. Boag (London) reported experiments on the decomposition of water and hydrogen peroxide by electrons and X-rays, showing that with neutral water there is no dependence on the intensity of the radiation, but that in acid solution the equilibrium concentration of hydrogen peroxide produced by large doses depends on the intensity. The mechanism proposed received some confirmation by further work on hydrogen peroxide produced in neutral aerated water by 30 and 220 kV. X-rays and 1·2 MeV. electrons by these workers in collaboration with Dr. M. Lefort (Paris and Leeds), H. C. Sutton (Leeds) and M. Ebert and Tikvah Alper (Hammersmith) using different analytical techniques. Dr. T. J. Hardwick (Chalk River) showed that, in the indirect action of X- and γ-radiation on aqueous ferrous and ceric sulphates, the yield varies with the initial energy of the ionizing electrons, and that this effect may be explained on the basis of existing theories of the primary action of ionizing radiation on water. The probability of the recombination of hydrogen atoms and of hydroxyl radicals was calculated as a function of the instantaneous electron energy.

Dr. E. Collinson and Prof. Dainton (Leeds) showed that the kinetics of the polymerization of aqueous acrylonitrile solutions induced by X- and γ-rays are strongly different from photochemical or catalysed reactions, and are consistent with an inhomogeneous distribution of the radicals formed from water, while at higher dose-rates an increasing degree of homogeneity is indicated. The three types of radiation used produced the same results. In heavy water (D_2O) solution irradiation leads to the formation of deuterium atoms which participate in the polymerization. In the discussion it was suggested that the unusual kinetics might in part be due to the insolubility of polymer in monomer.

The remaining papers dealt with more complex systems: Dr. G. Stein (Jerusalem) described the reactions of certain dyes in aqueous and non-aqueous systems, drew comparisons with biological systems and then discussed the role of the hydroxyl radical, free electrons and molecular oxygen in the radiation chemistry of organic substrates. Tikvah Alper (Hammersmith) reported experiments on the indirect inactivation of bacteriophage by ionizing radiations, and gave survival curves under various conditions. Dr. W. M. Dale (Manchester) discussed the possible protective effect of a second solute which may act as a competitive acceptor of free radicals, and the use of this effect, which is specific, as a measure of the protective power of various solutes. Dr. C. B. Allsopp and J. Wilson (London) showed that the quantity of indole decomposed in aqueous solution by X-rays increases with increasing concentration of indole and with decreasing dosage-rate. The radiation and the photochemical decompositions follow similar courses. Dr. W. Minder and H. Heydrich (Berne) discussed the results of their experiments on the irradiation of halogenated hydrocarbons in organic solvents, which show that the formation of halogen acids depends on the dose, the concentration of the solution, the number of halogen atoms in the compound and the type of binding.

The meeting was very successful on both the scientific and social sides, and may fulfil the hope expressed by Sir Charles Goodeve at the guest-night dinner that it would stimulate the development of radiation chemistry as much as a previous discussion many years ago had that of the closely related subject of photochemistry. The papers, together with discussion on them submitted in writing to the secretary, will appear later as a separate publication of the Faraday Society.

SCIENTIFIC EDUCATION OF PHYSICISTS

THE pamphlet "The Scientific Education of Physicists"*, recently issued by the Institute of Physics, is a report prepared by the Education Committee of the Institute which should act as a useful guide, for students who wish to enter the profession of physics and for those who have the responsibility of advising or teaching such students, to the facilities available for the education and training of physicists.

The Institute recognizes only two qualifications as satisfying completely the academic requirements for election to corporate membership—an approved degree from a recognized university, and the Institute's own graduateship examination—although partial exemption from the graduateship examination may be claimed by those who have previously obtained the Higher National Certificate in applied physics. In addition to the suitable degree courses at university institutions, the report refers to the several technical colleges which provide advanced courses in physics, usually for the external degree of the University of London, but it warns the intending student that very often such technical colleges, with the exception of the London Polytechnics and a few of the main provincial colleges, have poor facilities for teaching physics and very rarely do their resources extend to an honours course in physics. Moreover, since he will find it extremely difficult to obtain adequate financial assistance at a technical college, for the student who wishes to continue and do post-graduate research, usually leading to the M.Sc. or Ph.D. degrees, it is almost essential that he should study at a university institution. However, many of the major technical, as well as university, institutions do run excellent part-time courses, series of lectures and summer schools on advanced topics in physics which practising physicists will find of great value.

The report emphasizes the importance to the science-student of an ability to express himself clearly, concisely and easily in English, both in speech and in writing. Recent discussion in the press has not settled whether the admitted prevalence of a low standard in English among physics students is due to lack of attention at the school or at higher levels; but in the report it is attributed mainly to individual negligence. The report concludes with appendixes giving factual data relating to the individual physics departments of all the universities and university lleges of Great Britain and Northern Ireland and those technical colleges recognized by the Institute. most universities are now revising their regula- ons, the information given in the report should be ated with some caution. It is always wise for the tending student to make early and direct appli- tion to the university institution or college con- rned and to obtain the most up-to-date information. would have been a good thing if some such dication had been added to the report.

POSTERIOR PITUITARY GLAND

SYMPOSIUM AT CAMBRIDGE

A VERY informative session took place in the Physiological Laboratory, Cambridge, on June), when the Society for Endocrinology held a mposium on the posterior pituitary gland. This eeting was unique in the sense that so many of the eakers had made substantial contributions to our owledge concerning this gland, and that so much ore overall information is available for the posterior tuitary than any other endocrine gland.

The control of the secretion of the antidiuretic rmone was discussed from two different points of ew. Dr. P. A. Jewell and Prof. E. B. Verney gave account of their recent work dealing with the alization of the osmoreceptors. Intracarotid jection of hypertonic sodium chloride solution hibits water diuresis by causing release of the anti- uretic hormone. However, the exact site of the ceptor elements (osmoreceptors) stimulated by this pertonic solution is not known for certain. natomical investigation of the vascular bed of the ternal carotid artery showed that this vessel sup- ies the pituitary gland, the anterior hypothalamus cluding the greater part of the supraoptic and raventricular nuclei, as well as other parts of the osencephalon. Proof was given that the osmo- ceptors do not lie in the pars nervosa of the pituitary. e findings in an animal in which an internal carotid tery had been tied intradurally suggest that the ceptors lie in the prosencephalon. Dr. Mary Pick- rd emphasized that the supraoptic nerve cells, that ve rise to the majority of nerve fibres which supply e posterior pituitary, can be activated by different pes of stimuli, some arriving by nervous pathways, me being directly chemical, and some being physical physico-chemical. She described the release of tidiuretic hormone from the posterior pituitary and following injection of acetylcholine, nicotine, orphine and ferritin. Acetylcholine is rendered mporarily ineffective in this respect after appli- tion of di*iso*propylfluorophosphonate to the supra- tic nuclei. Intracarotid injection of adrenaline ven prior to an antidiuretic dose of acetylcholine gularly annuls the action of the latter. It is of uch interest that morphine is still effective in hibiting a high rate of urine flow if applied directly the supraoptic nerve cells, whether or not the olinesterase of the cells of the supraoptic nuclei ve been inactivated by di*iso*propylfluorophos- onate.

Prof. H. B. van Dyke, of the Department of armacology, College of Physicians and Surgeons, lumbia University, then dealt with the subject of sterior pituitary extracts. Ten years ago van Dyke, ow, Greep and Rothen[1] extracted a protein from e pars nervosa of the pituitary with the biological activities of both (antidiuretic – pressor and oxytocic) principles in about the same ratio as they are found in the gland. Its molecular weight was found to be about thirty thousand, and its biological activity was found to be low (1 unit = 61 μgm.). Although considerable evidence has been obtained that oxytocic and antidiuretic activities are present in constant ratios and that the protein is homogeneous, the possibility of adsorption of highly active principles on to an inert protein molecule has not been excluded. The highly purified principles recently isolated by du Vigneaud and his co-workers were discussed by Prof. van Dyke[2-5]. These principles have been isolated in a highly active form, 1 unit of the oxytocic principle being contained in 1·25 μgm. and 1 unit of the antidiuretic – vasopressor principle in 1·6 μgm. The amino-acid content of these two principles has been investigated, and it has been found that tyrosine, cystine, aspartic acid, glutamic acid, glycine and proline are common to both, whereas arginine and phenylalanine characterize the oxytocic principle and leucine and *iso*leucine characterize the antidiuretic – vasopressor principle. Using these principles, various workers have established that neither the contraction of the isolated rat uterus nor the ejection of milk by the lactating mammary gland is a specific test for the oxytocic principle, whereas the depressor response of the fowl's blood pressure appears to meet this requirement provided that contamination by antidiuretic – vasopressor principle is not excessive. The extremely sensitive antidiuretic test in the dog was found to be specific for the antidiuretic – vasopressor principle. It is not yet possible to decide from the published investigations whether the neurohypophysis secretes a large molecule containing both oxytocic and antidiuretic – vasopressor principles, or smaller molecules of highly active principles. The separate secretion of the latter has more teleological attraction.

In the next contribution, Prof. H. Heller dealt with the fate of the posterior pituitary (antidiuretic) hormone when secreted into the blood. Previous work had shown that antidiuretic extracts are rapidly inactivated by defibrinated blood, serum and liver homogenate. When injected intravenously the antidiuretic activity of posterior pituitary extracts disappears rapidly from the circulating blood, and antidiuretic activity appears in the urine. Recent unpublished experiments of Ginsburg and Heller have shown that the liver and kidney both play a part in the 'clearance' of the antidiuretic principle: it would seem that, in addition to excreting it, the kidney also removes it by another, as yet unknown, process. The question of the renal excretion of the antidiuretic principle, both of endogenous and of exogenous origin, was discussed in further detail.

B. A. Cross described the evidence underlying the present concept of a milk ejection reflex[6-8]. It can now be taken as established that the act of suckling stimulates a nervous reflex excitation of the posterior pituitary gland, and the secretion from this gland causes contraction of some element of the mammary gland and thus a positive ejection of milk from the mother to the young. Recent work using du Vigneaud's highly active oxytocic and antidiuretic extracts indicates that the posterior pituitary principle underlying milk ejection is the oxytocic principle and not a mixture of the two, as had been previously suggested. Mr. Cross also discussed unpublished work in which it was found that previous administration of adrenaline, or electrical stimulation of the posterior region of the hypothalamus with resultant sympathetic excitation, will inhibit the milk ejection reflex. Since the same procedures inhibit the milk ejection effect of posterior pituitary extract, it is likely that the effect of adrenaline is, at least in part, on the mammary gland itself. Dr. A. G. Lewis dealt with recent work on the secretion of the antidiuretic hormone in normal man. It is satisfying to know that many of the laboratory findings are being confirmed on the human. After eighteen hours of dehydration a normal subject had posterior pituitary hormone in the circulation with an antidiuretic activity equal to (approximately) 20 mU. of 'Pitressin'. It seems unlikely that the 5 mU./ml. of antidiuretic substance which have been detected by rat assay of human serum have any physiological action. Direct assay in the human subject has shown that human serum contains less than 0·1 mU./ml. after twelve hours of dehydration. Emotional stimuli, the intravenous infusion of acetylcholine, or of hypertonic saline, nicotine, morphine, anaesthesia and surgical operations and syncope may all produce large releases of the antidiuretic hormone in man.

The final speaker at the symposium, Dr. J. E. Cates, described the results of an investigation, in collaboration with Dr. C. Garrod, on fifteen patients with diabetes insipidus. 'Pitressin' tests separate the rare 'Pitressin'-resistant cases. Water deprivation gives results which vary in degree. Hickey and Hare's test with hypertonic saline may be nullified by an osmotic diuresis. Nicotine intravenously causes little or no antidiuresis when given in doses large enough to cause antidiuresis in normal subjects; larger doses usually cause some antidiuresis. The effect of nicotine in clinical diabetes insipidus supports the belief that nicotine stimulates the secretion of the antidiuretic hormone. The response to large doses suggests that the lesion to the supraopticohypophysial system is often not complete.

LONG ASHTON RESEARCH STATION

REPORT FOR 1950

THE plant pathologist and the engineer tend to run their separate ways, sparing a modicum of liaison for each other, but rarely understanding the subject of plant pathological engineering as a whole. The annual report of the Agricultural and Horticultural Research Station, Long Ashton, Bristol[*], is perhaps most noteworthy for a determined attempt to consider the problems of the plant pathologist and engineer together. H. G. H. Kearns and N. G. Morgan publish an abridged specification of an experimental 'air-flow' small-volume drift sprayer and duster. This is designed to investigate the most efficient method of conveying very small drops of concentrated control materials to their disease targets, thus dispensing wit
large volumes of liquid, obtaining better penetratic
of the spray or dust cloud into foliage, and with
bringing great economy of the fungicide or insecticid
This material is fed into the blast from a fan deliverir
a large volume of air at low pressure.

New conceptions must not, however, be allowed
overshadow the solid worth of papers on more usu
subjects. Nutritional studies include investigatio
on zinc and copper deficiencies of crop plants (E.
Hewitt and E. W. Jones), work on iron metabolis
in plants by the same authors contributing separa
papers, and research on molybdenum and nitra
status in relation to yield and ascorbic acid levels
cauliflower (S. C. Agarwala; W. Plant). The weal
of detail and of interaction in all these results
summarized in the introduction to the report by t
director of the Station, Prof. T. Wallace (pp. 13–15
L. C. Luckwill and D. Woodcock have a prelimina
report on the nature of the hormone whic
occurs in the endosperm of developing apple see
It is, *inter alia*, acidic, heat stable, soluble in eth
and water, is destroyed by hydrolysis with stron
acid or alkali, and cannot be identical with indoly
acetic acid. A further report on pruning systems an
tree shape on yield and quality of apples is given b
R. M. Jarrett. Any pruning reduces yield; but norm
winter pruning improves quality. Allington and Cox
Orange Pippins cropped better as modified lead
trees; but Worcester Pearmain gave more produce
an open-centre tree. Continuing their studies of th
nutrition of the black currant, C. Bould and E. Catlo
find that yield varied as leaf nitrogen status, whic
decreased according to the following order of manuri
treatments: nitrogen plus phosphorus > sewag
sludge > nitrochalk plus compost > straw slud
compost > farmyard manure > no manure. D. J.
Nicholas and W. A. Forster consider the effects
copper, zinc, lead, cobalt, nickel and manganese i
excess on tomatoes and other crop plants. This is a
important study, for excesses of 'micro' element
figure in advisory work in addition to deficiencies
these elements.

Long-term work on spray materials superior t
lime-sulphur for the control of apple scab has bee
continued by R. J. W. Byrde and R. W. Marsh. The
found that glyoxalidine 341-*C* at 1 quart per 10
gallons equalled the standard lime-sulphur treatment
on Cox's Pippin, and was less phytotoxic. The ne
spray was also less damaging to foliage of Lane
Prince Albert and Stirling Castle than lime sulphu
A phthalimide preparation (*SR*-406) promises goo
fungicidal performance and freedom from phyt
toxicity.

F. W. Beech and S. W. Challinor discuss chang
in the pectin and nitrogen contents of apple juices
a first part of a larger study of maceration an
defecation in cider making. Fermentation of cide
can also be controlled by centrifuging; L.
Burroughs and S. W. Challinor consider the mecha
ism of this action in some detail. B. T. P. Bark
continues his investigation of cider yeast floras wit
a paper on that of Kingston Black ciders. Margar
E. Kieser and A. Pollard discuss the effect of fru
storage on the processing of apple juice, and, wit
C. F. Timberlake, the effect of manurial treatment o
the composition of black currants. Other short
papers are included in the report, which is edited b
R. W. Marsh, and numerous half-tone and lin
illustrations help to maintain its usual high standa
of production.

Heat Flow through the Floor of the Eastern North Pacific Ocean

THE flow of heat through the earth's crust has en measured many times at various continental ations, and is usually found to lie[1] within 50 per 1t of $1 \cdot 2 \times 10^{-6}$ cal. cm.$^{-2}$ sec.$^{-1}$. Because of the sence of granitic rocks, with their relatively high dioactivity, in the crust under the oceans, it has en suggested that the heat flow through the deep- floor might be considerably smaller; but the ly data available from oceanic areas have been o measurements of the thermal gradient in deep- sediments reported by Pettersson from the edish *Albatross* expedition[2].

In 1949, Dr. E. C. Bullard spent the summer at Jolla in the preliminary development of an instru- nt for measuring temperature gradients in the sea or. During the following year, development of truments of the general type proposed by Dr. llard was continued under the direction of J. D. acs and J. M. Snodgrass, and in the summer of 50 a series of measurements was taken as part the work of the joint Scripps Institution of Oceano- phy – United States Navy Electronics Laboratory d-Pacific Expedition, on the Scripps research sel *Horizon*.

A hollow steel spear, 1·64 in. in outside diameter d 10 ft. long, was plunged vertically downward into bottom sediments and allowed to remain in place thirty to forty minutes. At its upper end the ar was attached to a heavy steel cylinder contain- a self-recording, self-balancing null potentio- ter which recorded continuously against time, to out 0·001° C., the difference in temperature be- een two thermal elements in the spear. The upper ment was situated 24·0 in. beneath the sea bottom, d the recording case, and the lower element 81·5 in. neath the upper element and 18·5 in. from the ar end. The thermal elements were connected rmally to the outside of the spear but were ulated electrically and protected from the outside drostatic pressure. We have satisfied ourselves m theory and experiment that the record of nperature difference against time obtained in this y can be extrapolated to give a value which responds within a few per cent to the undisturbed nperature gradient in the bottom sediment.

At each locality where the temperature gradient s measured, cores of the sediment were collected laboratory determination of the thermal con- ctivity; care was taken to preserve these samples as undisturbed a condition as possible and without ange in water content. The conductivity de- minations were made by D. W. Butler at the tional Physical Laboratory. Because of the high ter content of the sediments, the conductivities much lower than those in rocks and approach conductivity of sea water ($1 \cdot 3 \times 10^{-3}$ cal. sec.$^{-1}$.$^{-1}$ ° C.$^{-1}$).

The measured temperature gradients and thermal nductivities at six stations and the computed lues of the heat flow are given in the accompanying ole.

Latitude (North)	Longitude (West)	Depth of water (m.)	Temperature gradient (° C. m.$^{-1}$)	Conductivity (cal. sec.$^{-1}$ cm.$^{-1}$ ° C.$^{-1}$)	Heat flow (cal. cm.$^{-2}$ sec.$^{-1}$)
20° 48′	159° 42′	4,500	0·07	$1 \cdot 8 \times 10^{-3}$	$1 \cdot 3 \times 10^{-6}$
18° 18′	173° 23′	3,900	0·04	$2 \cdot 2 \times 10^{-3}$	$0 \cdot 9 \times 10^{-6}$
19° 28′	174° 35′	4,900	0·06	$2 \cdot 0 \times 10^{-3}$	$1 \cdot 2 \times 10^{-6}$
16° 45′	176° 24′	5,040	0·07	$1 \cdot 8 \times 10^{-3}$	$1 \cdot 3 \times 10^{-6}$
19° 02′	177° 19′	4,750	0·07	$1 \cdot 6 \times 10^{-3}$	$1 \cdot 1 \times 10^{-6}$
32° 35′	132° 30′	4,000	0·07	$1 \cdot 8 \times 10^{-3}$	$1 \cdot 3 \times 10^{-6}$

Although the number of measurements is small, it is noteworthy that at five of the six localities, covering a total distance of nearly three thousand miles, the computed heat flow lies within 10 per cent of the average value for the continents. From field evidence, it is likely that in the observation at long. 173° 23′ W. the spear did not penetrate completely into the sediment, and that consequently the recorded value for the temperature gradient at this locality is too low.

The heat flowing from the deep Pacific floor could represent at least in part a 'fossil' temperature gradient in the sediments, remaining from a time when the bottom-water temperature was higher than the present 1·60°. Short-period temperature fluctuations cannot be significant because observations indicate that deep-water temperatures in the North Pacific have remained constant within a few hundredths of a degree for the past twenty-five years. On the other hand, a markedly different climate five hundred to two thousand years ago might possibly have resulted in somewhat higher bottom-water temperatures in the tropics than those now prevailing. A bottom-water temperature of 4·5° one thousand years ago would account for half the observed gradient.

It might be supposed that the heat flowing from the deep-sea floor has been generated by processes within the sediments, such as biological activity, submarine weathering, radioactivity and compaction. Calculations show, however, that the total effect of these four processes cannot result in production of more than $0 \cdot 05 \times 10^{-6}$ cal. cm.$^{-2}$ sec.$^{-1}$—about 4 per cent of the observed heat flow.

If the heat flowing from the sea floor does not originate within the sediments, it must come from the underlying rocks of the earth's crust and mantle. Seismic refraction measurements made by R. W. Raitt on the Mid-Pacific expedition show that the Mohorovičić discontinuity between the crust and the mantle lies within five to nine kilometres of the sea floor. If the material above this discontinuity is similar in content of radioactive substances to oceanic basalt, then only 15 per cent of the observed heat flow can originate in the crust. If we also assume that the heat is carried from the earth's interior by conduction, and that following Jeffreys[3] the thermal conductivity is 5×10^{-3} cal. cm.$^{-1}$ sec.$^{-1}$ ° C.$^{-1}$, only some 20 per cent of the total heat flow can be accounted for by cooling of the earth. The remaining 65 per cent could be supplied by disintegration of radioactive substances in the mantle. But the required content of radioactive materials is so high that, if the radioactivity is uniform with depth or decreases exponentially, the mantle below about 130 km. would melt within a time short compared to 3×10^{9} years. It is therefore necessary to assume either that radioactive materials are concentrated in the outer part of the mantle under the ocean, or that the heat is being transported outward by convection in the mantle. If a steady state of convection exists, more than sufficient heat would be generated in a mantle having a uniform potassium content equivalent to that of stony meteorites[4]. In either case, however, we have the paradox that if the mantle under the continents is similar to that under the ocean, then the heat flow from the continents should be much higher than the observed value because of the presence of highly radioactive rocks in the outer parts of the continental crust.

A heat flow of $1 \cdot 2 \times 10^{-6}$ cal. cm.$^{-2}$ sec.$^{-1}$ through the ocean floor should noticeably heat the bottom-water masses as they flow northward from the Antarctic. With a velocity of northward flow of the order of 0·1 cm. per sec., as suggested by Sverdrup, Johnson and Fleming[5], the temperature of a layer of bottom water 1 km. thick would increase by about one-tenth of a degree centigrade on its journey from the region of sinking in the Antarctic to the tropics. This amount of heating would be largely masked by mixing with high-temperature water from above. But with the much smaller velocity of northward flow suggested by some recent workers, there should be a much larger increase in the bottom-water temperature between the Antarctic and low latitudes. Such an increase is not observed. The possibility exists, therefore, that our measurements are not representative of the heat flow through the sea floor. Obviously many more measurements must be taken before reliable generalizations can be made.

[2] Petterson, H., *Nature*, 164, 468 (1949).

[3] Jeffreys, H., "The Earth", 85, 2nd edit. (1924).

[4] Birch, F., *J. Geophys. Research*, 56, 107 (1951).

[5] Sverdrup, Johnson and Fleming, "The Oceans", 754 (1946).

The preceding communication by Revelle and Maxwell gives a result which is completely unexpected, and demonstrates again how little we know of submarine geology. Their observations do, I believe, demonstrate that the heat flow is roughly the same under the oceans and continents. It seems most unlikely that this is a temporary condition dependent on recent large changes in the temperature of the bottom water, for this is largely determined by the existence of ice in the Arctic and Antarctic. The ice cannot have melted since the last ice age, because the water from it would drown the greater part of the continents. It seems almost certain that the heat found by Revelle and Maxwell must be generated by radioactivity in the rocks beneath the oceans, and therefore that the total amount of radioactivity beneath unit area of continent and ocean is the same when summed down to a depth of a few hundred kilometres (heat generated deeper down has not had time to escape). This would be very surprising if the continents were formed from a primitive sialic layer not present under the oceans, and are underlain by material which is the same under continents and oceans. It would, however, be natural if the continents are continuously expanding by a process of differentiation in which radioactive material is concentrated vertically[1]. The rocks beneath the oceans would then have the same total amount of radioactivity as those beneath the continents, but spre through a greater range of depth; this would gi the same heat flow as beneath the continents, b higher temperatures at depth.

As is pointed out by Revelle and Maxwell, so upward concentration is necessary to avoid melti under the oceans. Calculation suggests that the radioactivity were spread through a depth 150 km., no impossibly high temperatures wou be produced. A possible interpretation of t results therefore appears to be that when t earth solidified most of the radioactivity was co centrated in the upper 150 km. of the mantle; und the oceans this distribution still exists, but und the continents a further concentration has occurr into the top 10 or 20 km. On this view it would expected that the oceanic ultra-basic rocks wou contain more radioactive material than th continental ones. There are few reliable measur ments; but those that do exist do not show such difference. This matter should be further investigate

Other explanations can be suggested. It migh for example, be supposed that at some not too remo time a convection current rose under the Pacific an brought hot material near the surface, or that th horizontal limb of a convection current had tran ported material from beneath the continents t the central Pacific. Such suggestions are pu speculation, and there is no other evidence in the favour.

The difficulties may be connected with that reconciling the oceanic seismic and gravity result The gravity results suggest that the material beneat the Mohorovičić discontinuity may not be quite th same beneath the continents and oceans in spi of the close agreement in seismic velocities. Som discussion of these matters is given in a book[2] to published shortly.

Use of a Gamma-Ray Pinhole Camera for *In vivo* Studies

The pinhole camera method of taking gamm radioautographs, though it has been described in th literature[1], has had very little use because of th long exposure times which are necessary even whe the most sensitive radiographic films are used. A intensifying screen for use with the pinhole camer has now been developed which has made it possib to reduce the exposure time considerably. The scree consists of a large, flat crystal of thallium-activate sodium iodide. The gamma-rays produce scintillatio in the crystal which in turn affect the photograph plate. This method has made it possible to take a *in vivo* gamma-ray pinhole radioautograph of tumour containing 20 millicuries of iodine-131.

A drawing of the pinhole camera and intensifyi screen is shown in Fig. 1. A gamma-ray from th object being photographed goes through the pinho and travels in a straight line until it enters th sodium iodide crystal, where it may produce a Compton or photoelectric recoil. The recoil electron trave about a millimetre or less in the crystal. The lig

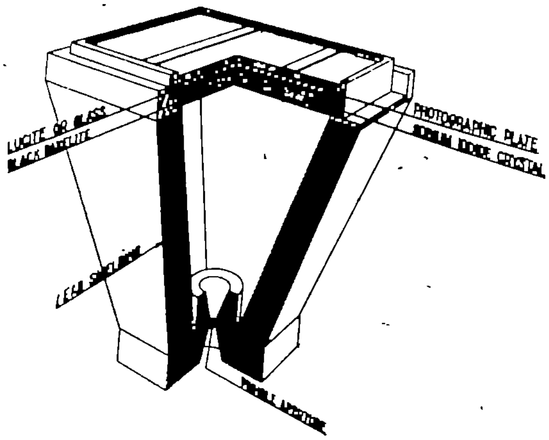

Fig. 1

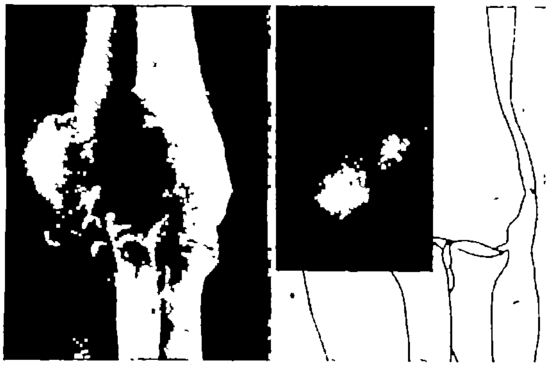
roduced along the path of the recoil is emitted sotropically. The spreading of the light over the hotographic plate and the consequent loss of definition are limited both by inverse square law attenuation and by total reflexion from the glass-to-air oundary between the crystal and photographic plate. he angle of total reflexion is about 35°. The light eflected from the glass surface passes back through he crystal and is absorbed by the black 'Bakelite' ontainer.

There is a considerable loss in definition due to preading of the light from the thick intensifying creen, even though it is limited as described above. n ordinary radiographic work this would not be ermissible; but due to the relatively poor definition btained from the pinhole camera, the additional loss n definition is relatively unimportant. In order to get ood optical contact between the crystal and the glass window, and also to protect the crystal from the ffects of moist air, it is contained in a bath of Monsanto Chemical Co. 'Aroclor No. 1248'.

The camera was tested by taking autoradiographs f bottles of iodine-131 solution. It was found that concentration of about 1 mC./cm.² and an exposure ime of 1 hr. were sufficient to give a faint but sable image of the source. This is about twenty imes less exposure time than is necessary if Kodak No-Screen film is used with the lead-foil intensifying creens customarily used for gamma-ray radiographs.

The exposure times given above are for the following conditions. The pinhole size was 1/8 in.; the inhole-to-intensifying screen distance 7½ in.; the ntensifying screen was a crystal of thallium-activated sodium iodide crystal 2 in. × 4 in. × 5/16 in. thick, obtained from the Harshaw Chemical Co., 1945 East 97th Street, Cleveland 6, Ohio; the photographic plate was a Kodak type 103a—0 spectroscopic plate slightly overdeveloped in *D*-19 developer.



(*a*) X-ray radiograph. (*b*) Pinhole autoradiograph

Fig. 2. Metastasis of thyroid tumour at elbow

As mentioned before, the camera has been used for taking an *in vivo* gamma-ray autoradiograph of a tumour containing iodine-131. The tumour was a metastasis of a thyroid carcinoma. It was close to the skin, had a volume of 90 ml.[1] and an area of about 20 sq. cm. The picture was taken 24 hr. after a therapeutic dose of 100 mC. iodine-131 was administered to the patient. It was determined independently that 20 mC. lodged in the tumour. A one-hour exposure was taken and the resulting picture is shown in Fig. 2*b*. The general outline of the area which took up the iodine-131 is shown, together with the fact that it is concentrated in two main areas. An X-ray radiograph of the tumour taken from the same point of view is shown in Fig. 2*a*.

I wish to acknowledge consultation with Dr. C. A. Tobias and also the assistance of Drs. Frank Pierce and Enrique Strajman in supplying information about the patient. This work was performed under the auspices of the Atomic Energy Commission, Contract W-7405-eng.-48.

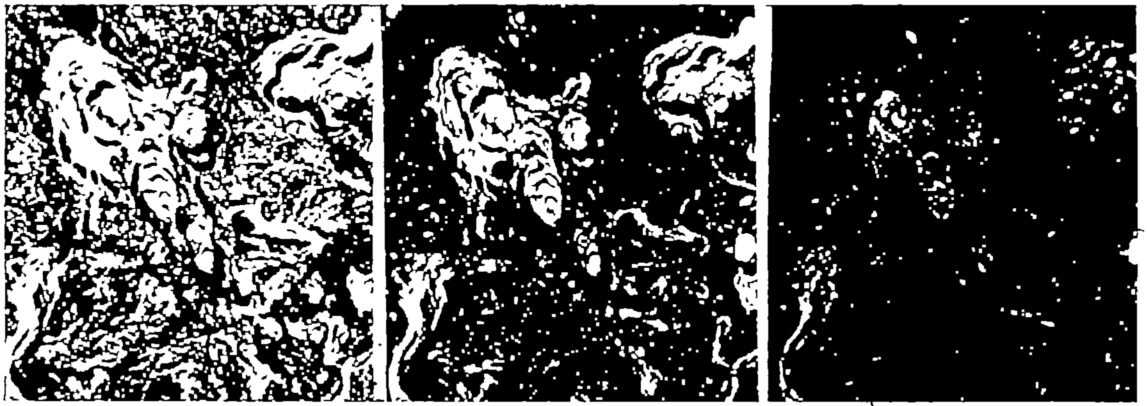
Microradiography with Alpha-Rays

ALPHA-PARTICLES are very strongly absorbed even by thin layers of materials. Their path through matter is almost exactly a straight line, and their effect on a photographic emulsion is very strong. These properties seem to be well suited for microradiographic mass determinations. Since such methods promise to be of value in several research fields, such as biology, medicine, mineralogy and metallurgy, experiments have been undertaken to determine the potentialities and optimal conditions for alpha-microradiography. The main advantage of using alpha-particles as compared with soft X-rays[1] would be the much simpler apparatus needed and the relative independence of the absorption on the composition of the object.

From purely geometrical considerations it is evident that to obtain high picture-resolution the alpha-particles must be collimated to normal incidence upon the object. Further, the object must be placed as near as possible to the photographic emulsion, and the grain-size of the emulsion should be small enough to allow the necessary enlargement. The collimation is most simply accomplished as in other types of radiography; the source of alpha-rays is placed at a distance from the object, which is large compared with the size of the source and the object.

When arranging for optimal mass resolution, that is, good contrast between areas differing in mass per unit area, the special mechanism of alpha-absorption must be borne in mind. The alpha-particles, being fast helium ions, are gradually slowed down



(1) (2) (3)

Alpha-microradiographs of a section 10 microns thick of cancer of the skin forming keratin (× 50.) The photographic density increases with decreasing mass per unit area

Source: 3·5 millicuries polonium-210, diameter 2 mm.; distance, source to object, 130 mm.; film, Lippmann emulsion 84·890 1 *M*; number of incident particles per square micron, 40

Energy of the alpha-particles entering the object corresponds to ranges of: (1) 0·6 cm.; (2) 1·1 cm.; (3) 1·6 cm. (in air at a pressure of 760 mm. mercury and a temperature of 15° C.)

through interaction with the electrons in the absorber. The number of elementary processes in this slowing down is sufficiently large to give a relatively low statistical variation (straggling) in the total range. This variation is only a few per cent of the total range, and is well represented by a Gaussian distribution.

An alpha-particle which has passed through a thin part of the object differs from one that has passed through a thicker part in that its residual range is greater, and it will thus penetrate deeper into the photographic emulsion. If the residual range of the alpha-particles after passing through the object is large compared with the straggling, the number of alpha-particles hitting unit area of the film is constant. The contrast is then solely dependent on the variation of photographic density with residual range. For normal incidence, it seems probable that this variation should be small except at small residual ranges. To obtain good contrast, the energy of the alpha-particles should thus be chosen so that they are almost completely stopped by the object. In this case, however, the straggling will be an important factor in the contrast produced, since a lower number of the alpha-particles will reach the film under thick areas than under thin areas. One would thus anticipate that the photographic density will vary with the thickness in a rather limited region of mass per unit area. On the other hand, the contrast should be very good.

The microradiographs chosen to illustrate this discussion were taken on the same object, the number of incident particles per unit area and the geometrical arrangement being held constant. The energy of the particles entering the object was varied by changing the air pressure in the space between source and object.

It is seen that in the thicker areas of the object the picture is white without contrast, and in the thinner areas the picture is uniformly black. In the intermediate regions the mass distribution can be measured by photometric comparison with the blackness under reference absorbers. The pictures show that by increasing the energy of the impinging particles the measurable region is moved towards thicker regions. By taking a sufficient number of radiographs with alpha-particles of varying energy, all the areas can be accurately measured. It is evident that all areas can be measured in one radiograph by using thin enough sections or an alpha-particle source emitting particles of a wide variety of energies. This means, however, sacrificing some of the mass-resolving power.

By using particles of homogeneous energy under oblique incidence, a large interval of linear dependence of photographic density on mass per unit area should be obtained. This, on the other hand, means sacrificing some of the resolution of the picture.

A more comprehensive publication concerning alpha-microradiography will be published elsewhere.

Diffraction Microscopy with X-Rays

In a recent communication, A. V. Baez[1] predicts the practical resolution obtainable by diffraction microscopy using X-rays. His prediction is based on the required conditions for making the hologram. Similar derivations were described by us at the International Conference on Electron Microscopy in Paris, September 1950, though unfortunately we are still awaiting publication of the proceedings of this conference. Our derivation relates to the application of the method to electron irradiation where lenses can be used for producing intense coherent sources or to magnify the diffraction image (hologram). Our results are immediately applicable to the X-ray case and lead to the same conclusions as reached by Baez.

The predictions made by Baez that a resolution approaching 10^{-8} cm. could be obtained by the use of a point source or a grainless film are somewhat misleading since neither case is a physical possibility. In practice, the resolution is determined by both the size of source and the resolution of the photographic plate. Conditions can be arranged so that the resolution obtained is approximately equal to half the size of the source or resolution of the plate, whichever is the smaller. This, in fact, represents no worthwhile nprovement in resolution over that which can be btained by direct methods, for a point projection licroscope will give a resolution equal to the size f source, and shadow microscopy (object in contact ith photographic plate) will give a resolution equal) that of the plate. The theory shows an apparent ain in resolution of 2 ×. There is some doubt, howver, whether this is a real gain or whether it is lost s a result of the use of coherent illumination; for xample, to resolve two coherent Airy patterns, twice he separation required for incoherent radiation is ecessary.

Surface Oxide Films in Intermetallic Contacts

Bowden and Hughes[1] have shown that removal f surface oxide films can endow metals with very igh coefficients of friction. To examine to what xtent these films, when present, prevent metallic ontact, electrical resistance measurements have een made on the loaded junction between crossed ylinders (½ in. in diameter) of various metals, their xes being perpendicular. The apparatus was designed o minimize vibration. The metallic constriction esistances have been calculated from theoretical onsiderations which have been discussed by Holm[2] nd plotted against the applied normal loads. Experimental curves for gold and silver between 10 gm. nd 10 kgm. agreed closely with the calculations. High resistances obtained with other metals indicated the presence of poorly conducting films in the contacts. Some of the curves could be explained quantitatively by assuming the films to be uniform and stable.

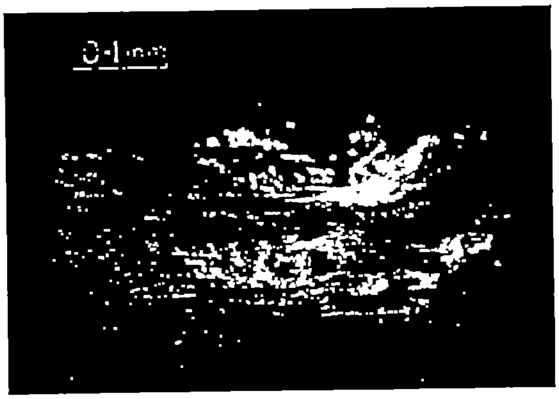

Fig. 2. Damage to stainless-steel cylinder; displacement increases from left to right

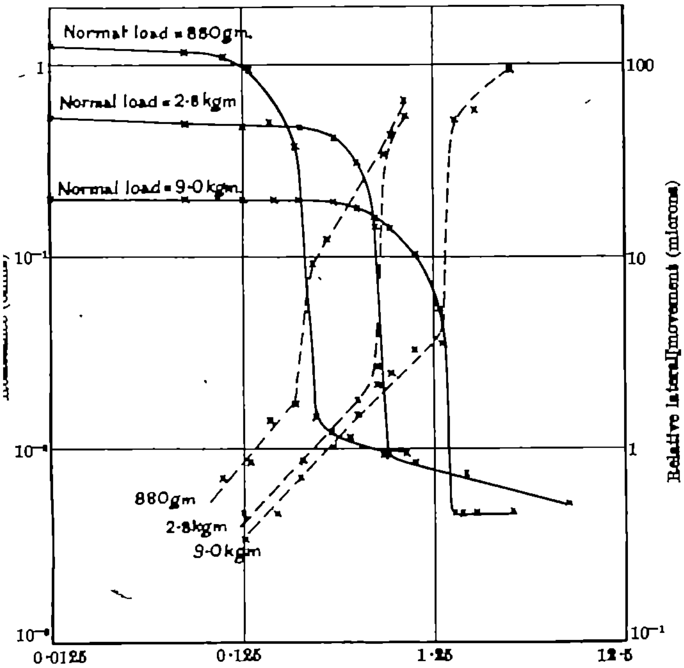

Fig. 1. Resistance *vs.* tangential force curves for stainless steel crossed cylinder contacts under various normal loads: ———, resistance; – – – –, lateral movement

With electropolished stainless steel and copper, the resistance remained high under loads up to 10 kgm. Fig. 1 shows the effect of applying an increasing lateral force (in the axial direction) to one of the normally loaded cylinders. The broken curves show the relative lateral displacement of the cylinders, measured by an optical lever device. Initially, the resistance was unaffected, and the small displacement could be attributed to strain in the cylinders and mountings. At a certain critical force, there was a fall in resistance accompanied by a sudden displacement. This force was much smaller than the usual friction force; but the resistance to motion increased rapidly with further displacement. The curves shown are for stainless steel; but those for copper are similar, except that the movement at the critical force is less sudden.

Microscopic examination showed that when the critical force was just exceeded, the damage to the contact surfaces was slight; greater lateral displacement rapidly increased the damage. With stainless steel, the damage formed a number of distinct tracks which later developed into torn patches (Fig. 2); but with copper the whole contact area became torn.

It has already been shown[3], using the radioactive method, that sliding enormously increases the transfer between metals in contact. The experiments described above show that the films on some metal surfaces are not penetrated under normal loading; a small lateral force is necessary to form metallic contacts. Subsequent lateral movement then raises the friction by increasing the area of intermetallic contact.

With cylinders lubricated by a thick layer of stearic acid, perceptible sliding began under a small force which did not increase very rapidly with displacement. The coefficient of friction could not be measured accurately, but was of the order of 0·01. Visible damage to the contact surface was confined to a few thin scratches. Fluctuations in resistance which accompanied any change in lateral displacement suggested that, when metallic contact was made, it was usually broken again by the lubricant. This supports the suggestion[4] that an important function of a lubricant is to prevent the growth of any small welds which may form.

Contrasting Methods of Transmission of Animal Viruses by Mosquitoes

RECENT investigations[1] of the mechanism of the transmission of myxomatosis of rabbits by mosquitoes have brought to our attention certain clear-cut differences between the transmission by mosquitoes of those diseases in which a 'biological cycle' occurs in the insect vector, and those in which carriage is purely mechanical. Among the animal viruses, it is only in fowlpox[2,3] and myxomatosis[1,4] that mosquito transmission has been conclusively shown to be mechanical in nature. In all the other mosquito-transmitted virus diseases that have been adequately studied (dengue, yellow fever, the viral encephalitides, and Rift Valley fever), there is a 'biological cycle' in the mosquito. Certain implications of these contrasting modes of transmission are summarized in the accompanying table.

	'Mechanical'	'Biological'
Source of virus	skin lesions	bloodstream
Specificity of mosquito-vector	nil	high
Interrupted feeding	positive	negative
Extrinsic incubation period (latent period)	none	present
Arthropod transmission the only natural mechanism	no	yes
Multiplication of virus in mosquito	no	yes

Mechanical transfer by mosquitoes may be expected to occur in any disease in which a high skin concentration of a relatively resistant virus occurs. It is not inconceivable that the 'airborne smallpox' reported around fever hospitals[5] was sometimes mechanically transmitted by mosquitoes, and cowpox may be spread thus among cows, as well as by the milker's hands. Similarly, swinepox may well be transferred from place to place by some more mobile mechanical vector than the hog louse[6]. Mechanical transmission is not incompatible with prolonged infectivity of the mosquito. Brody[3] obtained positive results with fowlpox at intervals up to forty-one days, and we found[1] that myxomatosis could be transmitted as long as twenty-five days after the infective feed.

If there is a viræmia but no deposition of virus in the skin, mechanical transmission by mosquitoes occurs only under exceptional conditions[7]. The data of Philip[8] and St. John *et al.*[9] appear to prove that the feeding mechanism of the mosquito is such that regurgitation does not occur. The opportunity for virus in the blood to contaminate the mouthparts appears to be slight, for in many diseases the virus is associated with the cellular elements of the blood, rather than circulating freely in the plasma[10,11].

Biting insects which are voracious 'pool feeders' may, on the other hand, be more likely to transfer virus present in the circulation, and this may be the explanation of the mechanical transmission of equine infectious anæmia by tabanid flies and *Stomoxy calcitrans*, but not by mosquitoes[12].

Appreciation of the features of mechanical and biological transmission of animal viruses shown in the table may help in elucidating the epidemiology of some of those diseases in which the role of insect vectors is not yet clear.

Non-random Distribution of Multiple Mitotic Crossing-over among Nuclei of Heterozygous Diploid *Aspergillus*

SOMATIC, or mitotic, crossing-over[1] occurs in nuclei of the mycelium of the homothallic ascomycete *Aspergillus nidulans*[2,3], made diploid and heterozygous for known markers by means of a new technique[4]. The asexual *Aspergillus niger* has now been found to behave in a similar manner; that is, diploids heterozygous for known markers give mitotic recombinants homozygous for one or more of these markers but usually still heterozygous for the others, and therefore undergoing further mitotic recombination. Detailed analysis of mitotic recombinants in *A. nidulans* further shows that mitotic crossing-over is not distributed at random between the nuclei of the mycelium but tends to be concentrated in a small proportion of them. The kind of evidence on which this conclusion is based is exemplified in the following paragraphs.

A diploid was used, having green conidia and no growth-factor requirement, of genotype

$$\frac{W \;\; ad_1 \;\; y}{w \;\; AD_1 \;\; Y} \;\; \frac{LYS}{lys} .$$

(W/w, coloured versus white conidia; AD_1/ad_1, independence of, versus requirement for, adenine; Y/y, green versus yellow conidia—these three loc linked in this order and with map distances of more than 50 cMo between w and ad_1, and about 7 cMo between ad_1 and y, w epistatic to Y/y. LYS/lys independence of, versus requirement for, lysine, non-linked to the others.) In the chromosome carrying e three linked genes the centromere is located tween *w* and ad_1.

On the theory of mitotic crossing-over[1], one expects at recombinants homozygous at one locus should usually homozygous also at other closely linked ci, especially if distal, but not usually at loci on e other arm of the same chromosome or on different romosomes. From a diploid of the genotype given ove, one would therefore expect that the homozygous recombinants should be mainly homozygous for i_1, which is proximal but only 7 cMo away, and the mozygous *w* mainly prototrophs, that is, still terozygous for ad_1 and for *lys*. In fact, recombina-on giving homozygosis for both *w* and ad_1 requires o disparate exchanges, one in each arm, and mozygosis for both *y* (usually with ad_1) and *lys*, for both *w* and *lys*, requires two exchanges, one each of two chromosomes.

The results of testing strains from individual een conidia, or from individual mosaic spots of llow or white colour, are as follows :

	Requiring :				Total tested
	adenine	lysine	both	neither	
Green	0	0	0	234	234
White	4	1	1	46	52
Yellow	13	0	2	1	16

he expectation that because of linkage most of e homozygous *y* should also be homozygous for i_1 is fulfilled (15 out of 16). That homozygosis for i_1 or for *lys* alone occurs rarely is shown by the ct that none of the 234 green shows it. That mozygosis for *w* or for *y* alone occurs rarely can seen by inspection of growing colonies of the iploid, where rarely are more than twenty recombin-nt mosaic patches or single heads found in a whole etri dish. A very crude estimate of homozygosis r ad_1 gives its occurrence as about once every mitotic divisions. Yet among the 52 homo-ygotes for *w*, 5 are also homozygous for ad_1, nd among the 68 homozygotes for *w* or/and *y*, 4 are lso homozygous for *lys*. Thus homozygosis at two more loci on different chromosome arms is far too equent to be accounted for by chance coincidence more than one exchange per nucleus.

Results with *Aspergillus niger* point in the same rection. In this species, however, while genetic alysis and experimental 'breeding' *sui generis* can ow be carried out with the present technique, we nnot cross-check the results of this analysis with ose of standard genetic analysis because of the bsence of a sexual cycle.

Incidentally, our work shows that mitotic crossing-ver occurs regularly if diploid nuclei are formed in ecies with an exclusively or mainly haploid life-cle. We see now that Sansome[4] was probably cor-ct when she suggested mitotic crossing-over as the use of certain results in her work on *Penicillium*. his raises the question of whether or not crossing-ver might be a general feature of chromosome nthesis. As diploid life-cycles evolved, it would ave become confined mainly to meiosis by the nergence of special mechanisms preventing it in matic cells.

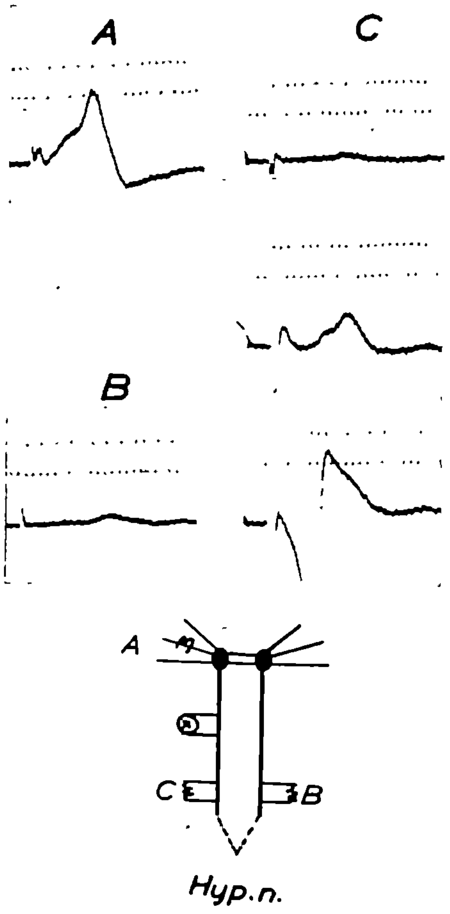
Excitation of Ganglion Cells in the Inferior Mesenteric Ganglion by Collaterals

WHEN the hypogastric nerve is stimulated with a current which is subthreshold for the postganglionic *C* fibres but sufficiently strong to stimulate the delta and *B* fibres, a number of cells in the inferior mesenteric ganglion are excited, and an impulse coming from the ganglion can be recorded in the hypogastric nerve. An impulse is also recorded on stimulation of the contralateral hypogastric nerve[1] (see diagram). If in a curarized preparation a conditioning tetanus is given preganglionically, a test shock to the post-ganglionic hypogastric nerve afterwards excites a larger number of ganglion cells. Now post-tetanic potentiation, also in the curarized ganglion, is exclusively localized to the stimulated fibres. Therefore these ganglion cells must have been excited through collaterals. This reflex persisted, when the afferent fibres, after bilateral excision of the spinal ganglions, Th 11—L VI, had been denervated. It was absent after sections and degeneration of the ventral roots of the same segments. Consequently, these collaterals are given off from efferent fibres which traverse the ganglion, and have their trophic centre in the spinal cord.

This is a confirmation of the tentative conclusion drawn by Langley and Anderson[1] concerning the pathway for the Sokownin crossed bladder reflex[2].



Stimulating electrodes on. (*A*) 2nd preganglionic nerve; (*B*) contralateral hypogastric nerve; (*C*) ipsilateral hypogastric nerve. increasing strength of stimulation. 500 c./s.

If the hypogastric nerve is stimulated with a current strong enough to excite *C* fibres, it was regularly found that a synaptically relayed impulse can be recorded in the colonic nerve and occasionally also in another branch of the hypogastric nerve. In some experiments on the curarized ganglion, these reflexes were potentiated after preganglionic tetanization with a current supra-threshold for *C* fibres. Therefore also *C* fibres which traverse the ganglion can give off collaterals capable of exciting the ganglion cells.

After bilateral denervation of the preganglionic nerves, a reflex in the colonic nerve can still be recorded on stimulation of the hypogastric nerve at *C* fibre strength. This finding is consistent with the anatomical and physiological data presented by Kuntz and Saccomanno[3].

Senility Changes in the Spinal Ganglion Neurones of the Toad, *Bufo regularis*

In a paper on fat, Ciaccio has figured various neurones, some of the toad, containing large spherical hollow bodies, which stain by Sudan III in formalin-fixed postchromed material.

Toads of different ages have been examined by various methods, among which the Kolatchew–Nassonow has provided a good series. The Golgi apparatus of the late tadpoles and the young toad is a canalicular reticulum which is polarized in th tadpoles (Fig. 1). In young toads few granules ar visibly attached to the osmiophile reticulum (Fig. 3 As the full-grown toad ages, it is possible to follo the break-up of the canals to form a variable numbe of large spherical and sub-spherical bodies show in the initial stage in Fig. 5. One such vesicle being formed at *X*, by the widening of the canal int a vesicle, and the thickening of one side. In Fig. the process of metamorphosis has become greatl advanced in the old toad, the Golgi reticulum havin nearly disappeared. In the senile condition (Fig. 9) th Golgi apparatus has completely degenerated into number of very large osmiophile vesicles (*v*), whic are more concentrated at the cell periphery. Thes osmiophile vesicles stain clearly in Sudan black in Regaud postchromed material, whereas the Golg reticulum does not so stain. It is clear, therefore that in old toads the Golgi material of the spina ganglion neurones is transformed into lipid. Beside the above-mentioned vesicles, pigment granules ar secreted by the Golgi apparatus; these granules ar situated in the cell body and finally migrate to th axon hillock region. The mitochondria in the spina ganglion neurones are granular. A further accoun of the material is being published elsewhere.

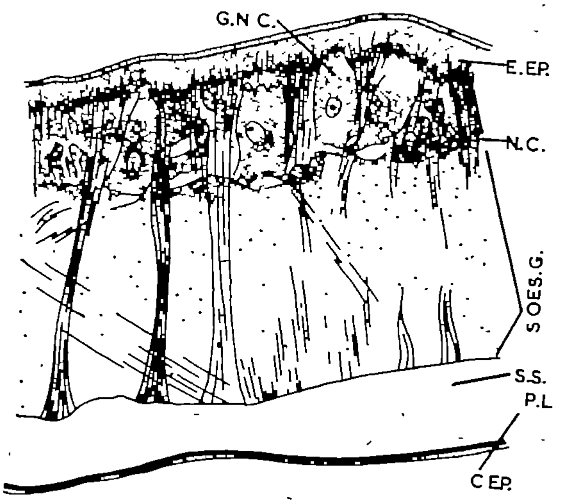
Giant Nerve Cells in *Lingula*

Elongated invertebrate animals which effect quic muscular contractions, either as a means of rapi withdrawal and escape like some Annelida[1] an Enteropneusta[2], or for the purpose of making sudde darts through the water like the macrurous Crustacea and the squids and cuttlefishes[4], have been show to possess giant nerve cells and fibres.

Fifty years ago, Morse[5] observed that the tw closely allied genera of ecardine Brachiopoda, *Lingul* and *Glottidia*, with long stalks by which they ar attached to the bottoms of their tubes in sand o mud, withdraw into their tubes with a quick jerk o an interruption of the light which falls upon them "The available descriptions of the nervous syste in the Brachiopoda give us a picture of the arrange ment in a few species but they do not supply in an point the modern demands. . . . About the for and nature of the nerve fibres we know only tha the fibre mass is a net-work of fine fibrillæ and tha the nerve cells like most cells of the Brachiopod are very small and therefore difficult to investigate."

However, working with fresh material fixed i Bouin's fluid, sectioned in paraffin and stained wit hæmatoxylin and eosin, I have found a small numbe of giant nerve cells in the suboesophageal ganglio of *Lingula* (see diagram). I hope, by the use of mor specific stains for nerve tissue, to be able to trac



Vertical section through the suboesophageal ganglion of *Lingula*. *C.EP.*, coelomic epithelium; *E.EP.*, epidermal epithelium; *G.N.C.*, giant nerve cell; *N.C.*, nerve cell; *P.L.*, pigment layer; *S.OES.G.*, suboesophageal ganglion; *S.S.*, supporting substance. (× *c.* 250)

he processes of these cells to the muscles of the stalk nd so to provide an explanation of the jerk noted by orse.

Lactic Oxidases of *Mycobacterium tuberculosis avium*

WE have previously discovered that the cell-free reparation of *Mycobacterium tuberculosis avium* akeo strain) catalyses the oxidation of lactate. ecently, we have confirmed that this preparation ontains two distinct lactic oxidases, and made clear e respective characteristic properties. One of these nzymes is a new type of lactate oxidative enzyme.

Enzyme activity was determined by measuring the xygen consumption manometrically in Warburg pparatus. Lactate, the substrate, was determined anometrically with ceric sulphate. The product, a olatile acid, was steam-distilled and titrated. yruvate, the other product, was determined by the sulphite-binding method of Clift and Cook and by e ceric sulphate method.

Mycobacterium tuberculosis avium, strain Takeo, as grown on the glycerol broth media. From the ompact mass of harvested bacteria, the crude cell-free nzyme preparation was obtained by alternating eezing and thawing. This preparation was able to xidize lactate with no addition. The addition of ethylene blue, however, increased by 30–50 per ent the consumption of oxygen. When the extract as heated for 10 min. at 50° C., the effect of methyle blue was not changed appreciably. Dialysis gainst water at 0° C. for 12 hr. had no effect on the xidation of lactate in the absence of methylene blue; ut in the presence of methylene blue the effect of is dye was abolished (Table 1).

Table 1. EFFECT OF HEATING AND DIALYSIS ON LACTIC OXIDATION BY THE CRUDE ENZYME PREPARATION

Enzyme preparation	Oxygen uptake (c mm.) per 60 min.	
	Without methylene blue	With methylene blue
Crude extract	101	210
Heated 10 min. at 50° C.	0	125
Dialysed 12 hr. at 0° C.	109	94

Warburg's vessels contain 2·0 ml. of enzyme preparation, 0 3 ml. of 0·2 *M* phosphate buffer (*p*H 6·2), and 0·2 ml of 3 *M* DL-lactate.

These phenomena indicate that the preparation includes two distinct lactic oxidases: one is heat-labile, stable in dialysis, and reacts directly with molecular oxygen, whereas the other is relatively heat-stable, labile in dialysis and active only in the presence of methylene blue. For convenience, we named the former 'lactic oxidase I' and the latter 'lactic oxidase II'.

The crude preparation (Q_{O_2} (per mgm. dry weight) = 15) was brought to *p*H 3·8 with acetic acid and the precipitate was dried in a desiccator *in vacuo* at room temperature. The dried precipitate was suspended in phosphate buffer. The extracted residue was removed by centrifugation, and ammonium sulphate was added to the supernatant solution (Q_{O_2} = 150), bringing the solution to saturation. Repeating the precipitation by acetic acid and ammonium sulphate alternately, the purified lactic oxidase I (Q_{O_2} = 450) was obtained. In the course of purification, lactic oxidase II was destroyed completely.

Lactic oxidase I. The purified lactic oxidase I oxidizes aerobically DL-lactate with no addition. Neither methylene blue, thionine, nor the cytochrome c and cytochrome oxidase system has any effect. The Michaelis–Menten constant is 5×10^{-2} mole per litre, using DL-lactate as the substrate. The optimum *p*H is about 6·2. Neither cyanide, azide nor 8-hydroxyquinoline has any inhibiting effect; but silver nitrate and copper sulphate both inhibit the reaction almost completely at a concentration of 3×10^{-4} mole per litre. This enzyme has no readily dissociable cofactor. Various coenzymes, for example, diphosphopyridine nucleotide, adenosine triphosphate, flavine mononucleotide and magnesium ions, were found to have no effect on the enzyme activity. However, flavine adenine dinucleotide often stimulated the catalysed reaction slightly.

Anticipating that the coenzyme of this enzyme might be flavine adenine dinucleotide, we heated preparations of various degrees of purification at 85° C. for 15 min., and the clear supernatant fluids were added to a mixture consisting of the apoprotein of pig kidney D-amino-acid oxidase and DL-alanine; the content of flavine adenine dinucleotide was measured by determining the oxidation-rate of DL-alanine. The oxidation-rate of alanine due to these preparations increased remarkably with the increasing degree of purification. It was presumed, therefore, that the prosthetic group of this enzyme is flavine adenine dinucleotide.

Oxygen consumed, and volatile acid and carbon dioxide produced, are all found to be one mole per mole lactate. The reaction catalysed by this enzyme can therefore be expressed by:

$$CH_3CHOH—COOH + O_2 \rightarrow CH_3COOH + CO_2 + H_2O.$$

This enzyme does not attack pyruvate, whether cocarboxylase is present or not, and also lactate oxida-

Table 2. CHARACTERISTIC PROPERTIES OF LACTIC OXIDASES

	Lactic oxidase I	Lactic oxidase II
Method of extraction	Alternate freezing and thawing	Autolysis from acetone powder
Heated at 50° C. for 10 min.	Labile	Stable
Dialysis	Stable	Labile
Precipitated with acetic acid	Stable	Labile
With molecular oxygen	Reacts directly	Reacts in the presence of carrier
With methylene blue or cytochrome *c*	Not affected	Affected; the enzyme requires them as carriers
Prosthetic group or co-factor	Flavine adenine dinucleotide	Diphosphopyridine nucleotide
Reaction product	Acetate	Pyruvate

tion is not inhibited by pyruvate. It appears, therefore, that this enzyme catalyses the oxidation of lactate to acetate and carbon dioxide with no intervention from pyruvate.

The addition of alcohol, azide, cyanide, hydrogen peroxide and active catalase prepared from beef liver, respectively, has no effect on the rate of reaction, and the addition of alcohol with strong liver catalase has no effect on the total amount of oxygen consumed and carbon dioxide produced. Consequently, we consider that the possibility of the formation of hydrogen peroxide is ruled out.

Lactic oxidase II. A larger amount of lactic oxidase II is contained in the acetone-powder extract than in the extract which is obtained by alternate freezing and thawing. Although we have not succeeded in purifying this enzyme, the activation by methylene blue, the cytochrome *c* and cytochrome oxidase system, and diphosphopyridine nucleotide was demonstrated with the acetone-powder extract. In the presence of methylene blue, pyruvate was detected as the reaction product. The reaction catalysed will be perhaps as follows:

$$CH_3CHOH\text{—}COOH + \tfrac{1}{2}O_2 \rightarrow CH_3COCOOH + H_2O.$$

The characteristic properties of the two distinct lactic oxidases are summarized in Table 2. As shown in the table, lactic oxidase I is a new type of lactate-oxidizing enzyme differing from the lactic dehydrogenases of animal tissues, yeast, *E. coli*, *Gonococcus* and higher plants. Lactic oxidase II is similar to the animal enzyme.

Growth of Rat Ovary in Tissue Culture

THERE are few reports of rat tissue cultures producing growth comparable to that from other mammalian species or from chick explants. Martinovitch[1], working with rat pituitary and rat ovary in watch-glass cultures, was able to keep the tissues alive *in vitro* for a considerable length of time; but cell outgrowth was comparatively slight. Abercrombie and Harkness[2] cultured regenerating rat liver. Fibroblasts or bile duct epithelium rarely grew from normal liver cultures, but appeared sporadically in cultures of regenerating material, the outgrowth varying with the state of liver regeneration. Only lymphocytes and granulocytes occurred in cultures regularly and in similar numbers regardless of the state of regeneration. The only case of rat pituitary tissue producing vigorous growth *in vitro* is that reported by Haymaker and Anderson[3].

In the present experiments it has been found that extensive epithelial growth can be obtained in slide cultures of rat ovary if the explants are kept in a fluid medium for 24 hr. before being placed in the slide cultures.

As a result of preliminary cultures, it was decided that rats 27–31 days old and approximately 60 gm. in weight were the optimum age from which tissues should be taken. Histological sections showed that in such ovaries follicular tissue was at a maximum.

Whole ovaries were removed from the rats and washed in Simm's solution containing 10 per cent rat serum. From each ovary, the larger follicles were gently squeezed, and then from the remaining piece of ovary ten to fifteen explants 1–2 mm. in diameter were cut. The expressed follicles, together with the larger ovarian explants, were transferred to an embryological watch-glass containing 2 c.c. of culture medium, which consisted of 50 per cent rat serum, 50 per cent rat embryo extract and streptomycin in the final concentration 0·0002 per cent. The watch-glasses were covered with large coverslips, sealed and incubated for 24 hr. at 37° C.

This 'preincubated' tissue was now cultured by the slide method. Explants were moored to the coverslip in a thin rat plasma-extract clot; a drop of fluid culture medium similar to that used for 'preincubation' was added and a meniscus drop culture finally prepared. Control cultures were prepared using fresh rat ovary in fresh medium. All cultures were incubated at 37° C.

After 24–48 hr. incubation, on an average, 75 per cent of the cultures of 'preincubated' tissue showed growth; after a further 24 hr. epithelial sheets of cells were prominent. By renewing the fluid medium, cultures could be kept healthy for up to seven days, the final width of the growth varying from 2 to 4 mm. On an average, 40 per cent of the control cultures grew and produced epithelium, but to a lesser extent than the experimental cultures.

The reasons for growth promotion and the beneficial properties of 'preincubation' are as yet undetermined. Rat tissue may be sensitive to injury, and injured cells fall from the explants, thus leaving healthy cells for culture. In transferring the explants to a fresh medium before culturing by the slide method, products of cell damage may be washed off. Slight separation of cells may occur during 'preincubation'. The effects of different culture media, and of duration and temperature of 'preincubation', require further study. The effect of 'preincubation' on the subsequent growth *in vitro* of other rat tissues should also be investigated since the optimum conditions for one tissue are not necessarily those required by other tissues.

This work was carried out during a short visit to the National Institute for Medical Research, London, and I wish to thank Sir Charles Harington and Dr. A. S. Parkes for making my visit possible. I am also indebted to Dr. A. U. Smith for many helpful suggestions, and for her stimulating interest in the work.

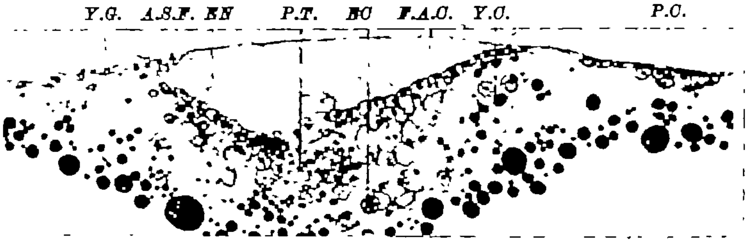
evelopment of the Embryonic Coverings in the Scorpion, *Buthus quinquestriatus* (H.E.)

DURING the period of proliferation of the embryonic ık of the scorpion (*Buthus quinquestriatus* (H.E.)), amnio-serosal fold appears at the anterior peri- ery (Fig. 1). The posterior margin of the embryonic ık up to this stage does not show any trace of ıher the serosa or the amnion. This is contrary the findings of Kowalevsky and Schulgin[1], who ımed that the amnio-serosal fold, in *Androctonus ıatus*, arises simultaneously around the whole ırgin of the embryonic disk.

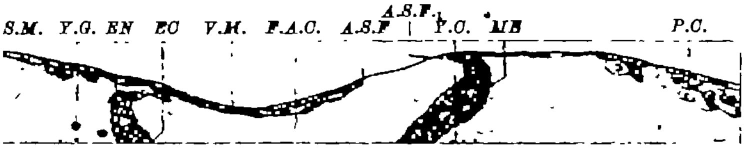
As development proceeds, the anterior amnio- rosal fold extends gradually backwards above the ture amniotic cavity (Fig. 2) and, at the same time, ong the margin of the germinal disk.

Also during the extension of the fold, the outer riphery of the upper layer extends beyond the rminal disk, just below the vitelline membrane, ıle that of the lower one is kept attached to the ıstoderm, which can be referred to, now, as the ıoderm.

At a later stage, the amnio-serosal fold continues development around the whole margin of the rminal disk and its edges fuse with each other to m two embryonic coverings, namely, the serosa d the amnion.



(1)



(2)

. 1. *Buthus quinquestriatus.* A longitudinal section in the embryonic disk of an early stage showing the anterior origin of the amnio-serosal fold. (× 225)

2. *Buthus quinquestriatus.* A longitudinal section in the side of an embryonic disk of a more advanced stage showing the extension of the amnio-serosal fold. (× 225)

.F., amnio-serosal fold; *A.S.F.₁*, marginal extension of the amnio-serosal fold; *EC*, oderm; *EN*, endoderm; *F.A.C.*, future amniotic cavity; *ME*, mesoderm; *P.C.*, primitive ıulus; *P.T.*, primary thickening; *V.M.*, vitelline membrane; *Y.C.*, yolk-cell; *Y.G.*, yolk granules; *S.M.*, serosa

The above description differs from those given by urie[2] in *Euscorpius italicus* and Brauer[3] in *Euscor- us carpathicus.* According to Laurie, the serosa velops, independently, before the amnion around edges of the blastoderm as a single layer of cells, ıich becomes reflected dorsally and grows gradually til its edges meet and fuse in the middle, just below vitelline membrane. The same author mentioned ıt the amnion appears from the edge of the blasto- rm shortly afterwards as a single layer of cells low the serous membrane. He further stated that serous membrane, at that moment, loses all con- xion with the blastoderm and then grows gradually around the yolk. The description given by Brauer is very near to that of Laurie.

Seasonal Change in the Humidity Reaction of the Common Earwig, *Forficula auricularia*

IN an investigation on physiological and ecological problems in *Forficula auricularia*, van Heerdt[1] found that well-fed, non-desiccated earwigs showed no humidity preference in the alternative chamber; but if previously desiccated, the earwigs became distinctly hygropositive. Whenever *Forficula* is found in dry places, its presence there is, according to van Heerdt, to be ascribed to thigmotaxis. Experiments begun in the winter of 1946–47 gave results closely resembling those of van Heerdt. In the summer of 1949, however, when the experiments were continued, the earwigs (both specimens taken directly from very dry natural conditions, and specimens kept in moist air even for weeks) showed a clear and strong preference for the drier side of the alternative chamber. Two-hour experiments were carried out in the day-time, but in darkness with the exception of short intervals for counting. With a choice between 100–34, 100–97, 100–99·5, 97–87, 77–34, 34–20 and 34–0 per cent relative humidity, the drier humidity was consistently preferred by the summer earwigs. Desiccation, however, caused even the summer earwigs to choose the moist air. These same specimens, well-fed and kept in a moist atmosphere all the time, so that the effect of desiccation was excluded, were investigated in the following winter. It appeared that the animals no longer showed the dry reaction, but tended now to prefer 100 to 34 per cent relative humidity. The experiments were repeated in the summer of 1950 and winter of 1950–51, with results similar to those obtained in the earlier years.

The accompanying table shows the difference in reaction in summer and winter, the intensity of reaction being expressed as the excess percentage, $\frac{100\,(W - D)}{N}$, on the moister side, where W represents the number on the moister side (100 per cent relative humidity), D the number on the drier side (34 per cent relative humidity), and N the total number of insects; + means reaction towards moist, and − means reaction towards dry. These experiments were carried out in the light.

	Time in minutes						No. of position records
	1–5	6–10	11–15	16–20	21–25	26–30	
Intensity of reaction during July–August	−49	−55	−53	−57	−67	−72	900
Intensity of reaction in January	+19	+37	+41	+64	+69	+66	1,800

These results are in full accordance with the ecology of the species. It is well known[2] that in the autumn earwigs burrow into the soil for hibernation and egg-laying, the fresh soil in the burrows keeping the air constantly humid. In view of this the disappearance of the strong dry reaction of the summer earwigs in the winter is quite understandable. These results, however, still need confirmation with earwigs taken directly for experiment from their burrows in the soil in the winter.

These investigations on the humidity sense in *Forficula* will be continued, and the results will be published fully elsewhere.

My thanks are due to Prof. J. E. Harris for help and facilities in the Zoological Department, University of Bristol.

Maximum Molecular Weight of Insulin

CURRENT investigations on the molecular weights of enzymic digests of insulin prompted the redetermination of the sedimentation and diffusion constants of the untreated crystalline protein. This work has given results which differ considerably from the previously published figures for this substance[1].

In phosphate buffer, *p*H 7·4, the mean of seven determinations in the Spinco ultracentrifuge gave $s_{20,w} = 3 \cdot 12 \pm 0 \cdot 02$ (S.D.) Svedberg units. This value was independent of concentration in the range 0·4–0·8 per cent, of temperature in the range 17–26° C., and of ionic strength in the range 0·10–0·30. The experimental details of operation of the ultracentrifuge were as previously described[2,3]. Diffusion coefficients were determined with the Gouy diffusiometer[4], the use of which with proteins has recently been discussed[5]. At *p*H 7·4, and ionic strength 0·10, the results shown in the accompanying table were obtained.

The diffusion coefficients given are the means of two, or more generally four, determinations, and are expressed in units of 10^{-7} cm.^{2} sec.$^{-1}$. They we independent of temperature in the range 14–30°

DIFFUSION COEFFICIENTS OF INSULIN AT *p*H 7·4

Concentration (per cent)	$D_{20,w}$	Concentration (per cent)	$D_{20,w}$
0·181	9·57	0·300	8·50
0·196	9·03	0·328	8·23
0·238	8·74	0·380	8·23
0·257	8·91	0·482	8·34
0·266	8·77	0·684	8·28

The values were calculated from the movement the outermost interference minimum in the expe mental record, which gives a D_A average; calculati of D_m for the most concentrated solution by t method of Ogston[5] gave 8·16 for this quantity. T diffusion behaviour, therefore, approximates to t ideal at this concentration.

This work provides qualitative confirmation f the dissociation phenomena reported from osmot measurements by Gutfreund[6], for concentratio lower than about 0·3 per cent, but gives a differe value for the molecular weight in the stability rang Thus, using the values $s = 3 \cdot 12$, $D = 8 \cdot 2$, applicati of the Svedberg equation gives $M = 34{,}800$ f $\bar{v} = 0 \cdot 735$ (see Pedersen[1]), or 36,700 on the older valu $\bar{v} = 0 \cdot 749$. Gutfreund[6] obtained $M = 48{,}000$ und these conditions.

The value of 35,000–36,000 refers to the maximu molecular weight of insulin as it exists in soluti (investigations at *p*H 7·0 and 7·2 gave similar result and so is in satisfactory agreement with the X-r determination[8] of the molecular weight in the sol state, namely, 36,000.

At *p*H 8·0, lower values of the sedimentation co stant and higher values of the diffusion coefficie have been obtained; details of these and oth results will be included in a full account of this wor to be published shortly elsewhere.

A Synergistic Interaction between 3-Indolylacetonitrile and 3-Indolylacetic Acid

EXPERIMENTS carried out with 3-indolylacetonitril recently isolated by Jones, Henbest, Smith a Bentley[1] from brussels sprouts, have indicated th the substance may function either as a plant grow regulator or can be converted within the plant to substance with growth-regulating properties.

Some experiments carried out in this Departmen with a pure sample of the 3-indolylacetonitrile, kind supplied by Prof. E. R. H. Jones of Manchester, we designed to substantiate a further explanation f the activities shown by this compound.

Jones *et al.* have stated that in the *Avena* straigh growth test the nitrile is more active than t corresponding 3-indolylacetic acid and have sho that a 10-mgm./l. solution of the nitrile in the presen of *Avena* coleoptiles may produce, in twenty-fo urs, an acid with an activity equivalent to a con- tration of less than 0·1 mgm./l. of 3-indolylacetic d. If the nitrile was broken down to the acid by plant, it is clear from the results quoted by these rkers that up to 50 per cent of the elongation due the nitrile at 10 mgm./l. could be ascribed to the version of the nitrile to 3-indolylacetic acid. veral possible explanations have been proposed by se workers to account for the greater activity wn by the nitrile in this test. First, the nitrile elf may be active, and the resultant elongation is summation of the effects of the nitrile and the d. Secondly, the plant cells may be more permeable the nitrile than the acid and this, coupled with breakdown of nitrile within the cells, might lead a higher internal concentration of acid than that ained if the tissue was immersed in the acid alone the same concentration. There would appear to be further possible explanation. The nitrile could inactive, but might act as a synergist to 3-indolyl- tic acid present naturally within the plant tissue formed by the breakdown of the nitrile. Thus, the ta of Jones *et al.* could be interpreted as follows. to 50 per cent of the activity of a 10-mgm./l. ution of nitrile could be due to conversion to the d, while the remaining activity could be attributed a synergist effect of the nitrile upon the 3-indolyl- tic acid.

In the standard Went pea curvature test[2] Jones *al.* found that the nitrile was inactive at concentra- ns below 20 p.p.m., indicating that any breakdown 3-indolylacetic acid which may have occurred at se concentrations was too small to be detected by assay. The rigorous proof of synergism between o active compounds is often difficult, but such interaction can be more readily demonstrated if of the compounds concerned is inactive. For se reasons experiments were carried out with pea sue in preference to *Avena* tissue to determine ether, in fact, the nitrile could act as a synergist applied 3-indolylacetic acid.

DEGREE OF CURVATURE OF SPLIT PEA EPICOTYLS
(Went standard test)
rvatures shown as mean number of degrees, ± standard error)

3-Indolylacetic acid concentration—p.p m.	3-Indolylacetonitrile concentration—p.p.m.		
xperiment 1	0	20	
0	0	0	
0·1	2 ± 1	57 ± 11	
1 0	108 ± 10	157 ± 9	
2·5	120 ± 5	159 ± 12	
xperiment 2	0	5	50
0	0	0	25 ± 6
0·1	2 ± 1	7 ± 4	81 ± 11
0·5	34 ± 5	38 ± 8	136 ± 12
1·0	65 ± 7	95 ± 10	127 ± 12

The results for two experiments are given in the le. In concentrations up to 20 p.p.m. the nitrile luced no positive curvatures. At each concentration 3-indolylacetic acid, the addition of 20 p.p.m. of nitrile resulted in an increase in curvature which statistically significant. With 5 p.p.m. of the rile, the increase is small and non-significant, but still positive. At 50 p.p.m. the nitrile itself ex- its some activity but the curvature produced is s than that given by 0·5 p.p.m. of 3-indolylacetic d alone. When, however, 50 p.p.m. of the nitrile combined with 0·5 p.p.m. of the acid, the curvature tained is significantly greater than that produced 1·0 p.p.m. of 3-indolylacetic acid. Thus the evidence for synergism between these compounds in pea tissue seems clear, and it is therefore suggested that the synergistic or hemiauxin activity of the nitrile in the presence of 3-indolylacetic acid is a further factor for consideration in assessing the growth-regulating activity shown by this new plant product.

Hydrogen Transfer by Thiols

THE thermal decomposition of α,α'-azoethylbenzene in inert solvents at 125° C. leads, apart from a quantitative production of nitrogen, to methylbenzyl radicals which combine to meso and racemic 2,3-diphenylbutane. Disproportionation of the radicals does not occur since ethylbenzene could not be detected (1).

$$C_6H_5(CH_3)CH{-}N{=}N{-}HC(CH_3)C_6H_5 \rightarrow N_2 + 2\,C_6H_5(CH_3)\dot{C}H \qquad (1)$$

However, in the presence of a twice molar proportion of a thiol such as *n*-octane-1-thiol or thiophenol, dehydrogenation to phenyl methyl ketazine takes place, the amount of nitrogen evolved in the course of the reaction dropping to about 58 per cent (2, 3). Part of the methylbenzyl radicals formed is hydrogenated to ethylbenzene, the balance giving 2,3-diphenylbutane or other products. Apparently, thiyl radicals are more reactive than methylbenzyl radicals, since they are capable of abstracting a hydrogen atom from the azo compound, eventually converting it into the ketazine.

$$C_6H_5(CH_3)\dot{C}H + R\mathrm{SH} \rightarrow C_6H_5(CH_3)CH_2 + R\mathrm{S}\cdot \qquad (2)$$

$$2\,R\mathrm{S}\cdot + C_6H_5(CH_3)CH{-}N{=}N{-}HC(CH_3)C_6H_5 \rightarrow 2\,R\mathrm{SH} + C_6H_5(CH_3)C{=}N{-}N{=}C(CH_3)C_6H_5 \qquad (3)$$

Active hydrogen donors like 9,10-dihydroanthracene, which scarcely react with methylbenzyl radicals, are readily dehydrogenated to compounds like 9,9′,10,10′-tetrahydrodianthranyl-9,9′, in the presence of thiols (4, 5).

$$R\mathrm{S}\cdot + \mathrm{H}D \text{ (hydrogen donor)} \rightarrow R\mathrm{SH} + D\cdot \qquad (4)$$

$$2\,D\cdot \rightarrow D_2$$

Hydrogen donor and azo compound will compete for the thiyl radicals, the amount of nitrogen evolved being a measure of the reactivity of the former. In the system α,α'-azoethylbenzene (1 mole), *n*-octane-1-thiol (2 moles) and 9,10-dihydroanthracene (1 mole), the amount of nitrogen evolved is increased to 98 per cent again.

It was found that only one mole of thiol disappears for every four moles of ethylbenzene formed, thus showing that the thiol acts as a hydrogen transfer agent.

Other aliphatic azo compounds, for example, 2,2′-azo-*iso*butyronitrile, can also be used for the dehydrogenation of active hydrogen donors when thiols are present.

In view of the ready formation of thiyl radicals from thiols even by relatively inert radicals—as is evident from the extremely high chain-transfer constants in vinyl polymerization[1]—the above high reactivity of RS radicals with respect to dehydrogenation would seem surprising. Thus, the heat of reaction of (6) should be equal to the sum of the heat effects of (2) and (4), although (6) would appear to be very much slower.

$$C_6H_5(CH_3)\dot{C}H + HD \rightarrow C_6H_5(CH_3)CH_2 + D \qquad (6)$$

However, a close parallel between heats of reaction and activation energies can be expected only in the case of closely analogous reactions, that is, reactions involving the same reacting functional groups. Thus, it may well be that in the reactions (7) and (8) the relationship between activation energy and heat of reaction is quite different from that in hydrogen abstractions involving only hydrocarbons and hydrocarbon radicals.

$$R_1\cdot + R_2SH \rightarrow R_1H + R_2S\cdot \qquad (7)$$

$$R_2S\cdot + R_3H \rightarrow R_2SH + R_3\cdot \qquad (8)$$

Furthermore, it seems conceivable that the fast rate of (4) as compared with that of (6) is merely due to a higher concentration of the RS radicals as compared with that of the methylbenzyl radicals. On the other hand, such a difference should be caused by a faster rate of dimerization of the methylbenzyl radicals as compared to that of the RS radicals, which seems somewhat unlikely.

The above results suggest that the activation energies of reactions of type (7) and (8) are rather low. In consequence, these reactions might well be reversible even at room temperature. As a result, they may play an important part in biochemical oxidation and reduction processes.

A detailed account of this work will be published in the near future. Our thanks are due to the management of the Bataafsche Petroleum Maatschappij for permission to publish this communication.

Thiol Catalysis of the Homolytic Decomposition of Aldehydes

The homolytic decarbonylation of aliphatic aldehydes regularly occurs at elevated temperatures in the vapour phase[1]. We have studied this reaction with a number of aliphatic aldehydes in the liquid phase at 90°–120° C., using the $Me_2\dot{C}—CO_2Me$ free radical (produced by the thermal decomposition of dimethyl-2 : 2′-azo-*iso*butyrate) as the initiating catalyst, and have found that only about 5 per cent of these radicals are effective as dehydrogenators (1).

$$Me_2\dot{C}—CO_2Me + R—CHO \rightarrow Me_2CH—CO_2Me + R—\dot{C}O \qquad (1)$$

Only a short reaction chain (2–3) can be concerned in the liberation of carbon monoxide, and this is probably terminated by (4).

$$R—CO\cdot \rightarrow R\cdot + CO$$ (

$$R\cdot + R—CHO \rightarrow R—H + R—CO\cdot$$ (

$$R—CO\cdot + Me_2\dot{C}—CO_2Me \rightarrow R—CO—CMe_2—CO_2Me$$ (

Even when the molar proportions of aldehyde
azo ester are as low as 5 : 1, the amount of carb
monoxide evolved was never more than that of t
nitrogen formed from the azo-compound : the ave
age extent of aldehyde decomposition was less th
8 per cent, and benzaldehyde gave no carb
monoxide. Carbon tetrachloride, with which R—C
radicals react easily, was a very effective inhibit
of the chain process (2–3).

Our results accord with those of Winstein a
Seubold[2], who effectively decarbonylated β-phen
*iso*valeraldehyde at 130° using *t*-butyl peroxide
the radical-producing catalyst, but reported th
benzoyl peroxide at 80° initiated very little actio
By using the more active $CH_3\cdot$ radicals from acet
peroxide at 65°, Kharasch, Urry and Kuderna[3] hav
however, reported up to 20 per cent decarbonylati
of aldehydes even in the presence of olefins. Fro
the small extent of the decarbonylation at modera
temperatures, it can be inferred from all these observ
tions that some at least of the reactions (1–
must require a significant amount of activati
energy.

When, a few months ago, Drs. Kooijman and Bick
of the Koninklijke/Shell Laboratorium, Amsterda
kindly informed us that thiyl radicals, Alk—S·, we
more effective dehydrogenators of 9 : 10-dihydr
anthracene than were α-methyl-benzyl radicals[4],
investigated the effect of adding a little benz
mercaptan to mixtures of aliphatic aldehydes a
azo-compounds and obtained quite striking resul
The addition of as little as 0·5 mol. per cent of t
thiol to our mixtures increased the extent of aldehy
decomposition, as measured by carbon monoxi
evolution, to 80–90 per cent for α-branched aldehyd
such as 2-ethyl-hexanal, and to a lesser but st
marked extent with *n*-aldehydes. Hence the cha
sequence :

$$Me_2C—CO_2Me + Tol—S—H \rightarrow Me_2CH—CO_2Me + Tol—S\cdot$$ (

$$Tol—S\cdot + R—CHO \rightarrow Tol—S—H + R—CO\cdot$$ (

then (2) followed by

$$R\cdot + Tol—S—H \rightarrow R—H + Tol—S\cdot$$ (

must be much more effective than the reaction cha
(1–4) above, and, in particular, (6) and (7) must
more effective than (1) and (3).

If current bond-strength values are taken for C—
and S—H links, then (5) and (7) should be exother
and (6) decidedly endothermic, whereas (1) and
should be nearly thermoneutral, though it is possi
to explain the exothermicity of reactions (1), (3) a
(6) by ascribing large resonance stabilization to t
R—CO· free radical. The resonance concept d
not, however, account for the greater ease of occ
rence of the chain (5–7), and, as our Dutch collea
have pointed out[4], it would seem that in our reacti
too, the activation energy required for attaining t
transition state

$$R_1—S \ldots H \ldots CR_3$$

may be less than for the hydrogen transfer betw
hydrocarbon radicals

$$R'_3C \ldots H \ldots CR_3.$$

The scope of this thiol-catalysed decarbonylation f aldehydes is now under investigation, and details ill be submitted for publication in the near future. t is also proposed to search for other instances of ehydrogenation by thiyl radicals, R—S·, since the entative speculation made by one of us some years go[4] that thiol-containing enzymes may act by prooting homolytic dehydrogenation may now prove o be capable of exemplification with simpler organic olecules.

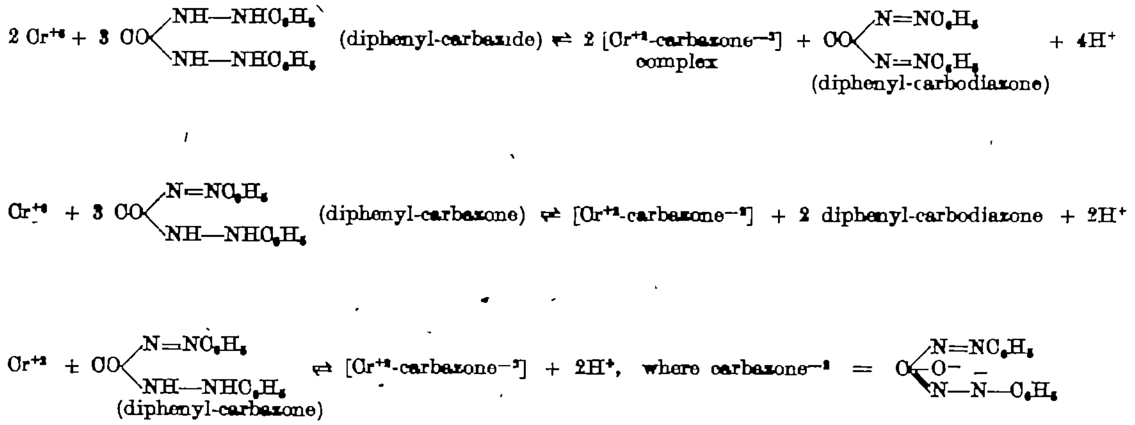
Mechanism of the Reaction between Dichromate and Diphenylcarbazide

THE colour reaction between dichromate and dihenylcarbazide in acid medium is the basis of the est method yet devised for the detection and colorietric estimation of small amounts of chromium. ccording to Cazeneuve[1], the intense colour is unoubtedly due to an organo-metallic chromium omplex. Attempts were made by Moulin[2] to isolate he compound but without any success. Thus the echanism of the reaction has remained unknown.



$$2\,Cr^{+6} + 3\,CO\begin{matrix}\diagup NH{-}NHC_6H_5\\ \diagdown NH{-}NHC_6H_5\end{matrix}\ \text{(diphenyl-carbazide)} \rightleftharpoons 2\,[Cr^{+2}\text{-carbazone}^{-2}]\ \underset{}{\text{complex}} + CO\begin{matrix}\diagup N{=}NC_6H_5\\ \diagdown N{=}NC_6H_5\end{matrix} + 4H^+$$

(diphenyl-carbodiazone)

$$Cr^{+6} + 3\,CO\begin{matrix}\diagup N{=}NC_6H_5\\ \diagdown NH{-}NHC_6H_5\end{matrix}\ \text{(diphenyl-carbazone)} \rightleftharpoons [Cr^{+2}\text{-carbazone}^{-2}] + 2\ \text{diphenyl-carbodiazone} + 2H^+$$

$$Cr^{+2} + CO\begin{matrix}\diagup N{=}NC_6H_5\\ \diagdown NH{-}NHC_6H_5\end{matrix} \rightleftharpoons [Cr^{+2}\text{-carbazone}^{-2}] + 2H^+,\ \text{where carbazone}^{-2} = C\begin{matrix}\diagup N{=}NC_6H_5\\ -O^-\\ \diagdown N{-}N{-}C_6H_5\end{matrix}$$

(diphenyl-carbazone)

In the present work, attempts have been made to lucidate the mechanism of the reaction from different hysico-chemical points of view. It has been noted hat, for the reaction to occur, the chromium must e in the hexavalent state. This leads to the conlusion that it must be a redox reaction, and possibly lso coupled with complex formation. Chromium n the tervalent state fails to react with either iphenylcarbazide or its oxidation product diphenylarbazone, but hexavalent chromium reacts with oth, producing the same colour reaction. However, hromium in the bivalent state reacts with diphenylarbazone to produce the same colour reaction, but ils to react with freshly prepared carbazide which free from carbazone. Excess of chromous ion or xcess of dichromate ion destroys the colour, probably owing to the reduction of carbazone to the carbazide in the first case and oxidation of the carbazide to its higher oxidation product carbadiazine, or even further, in the latter case. The spectral curves of three different systems, namely, chromate–carbazide, chromate–carbazone and chromous–carbazone are found to be identical, having an absorption maximum at 540 mμ.

A quantitative study of the reaction from spectrophotometric measurements was made by the method of Job[3]. For mixtures of chromate–carbazide and working with equimolecular solutions, the maximum reaction was found to correspond to a ratio of chromate to carbazide of 2 : 3. For the chromate–carbazone reaction this ratio was 1 : 3 and for chromous–carbazone mixtures it was found to be 1 : 1.

These observations can be explained by the accompanying reactions.

Transport measurements on concentrated solutions of mixtures of chromate and carbazide showed the compound to be of a non-electrolytic type. This is also in conformity with the above formulation of the compound as an inner metallic chromium complex.

That the compound formed contains chromium in the bivalent state is corroborated by magnetochemical methods. Magnetic susceptibility measurements were made with solutions of chromate–carbazide mixtures in which the ratio of chromate to carbazide was 2 : 3 (corresponding to the maximum composition in Job's method, where as a first approximation it can be considered that the complete conversion of chromate to the chromous complex has occurred). The solution was found to be paramagnetic, and calculation gave a susceptibility of 4·5 Bohr magnetrons for the moment of chromium, which is undoubtedly due to bivalent chromium.

Details of the mechanism of the reaction and its kinetics will be published elsewhere.

My thanks are due to Prof. P. B. Sarkar for his interest and kind encouragement, and to Dr. B. C. Haldar for his helpful suggestions during the progress of the work.

FORTHCOMING EVENTS

Wednesday, August 6—Friday, August 8

FARADAY SOCIETY (in the Department of Zoology, The University, Cambridge)—General Discussion on "The Physical Chemistry of Proteins".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT STATISTICIAN (preferably holding a degree in economics with statistics) in the Department of the Commercial Manager—The Secretary, East Midlands Gas Board, Beverley House, University Street, Leicester (August 12).

STATISTICIANS in the Department of Census and Statistics, Ceylon—The Office of the High Commissioner for Ceylon in London, 13 Hyde Park Gardens, London, W.2 (August 13).

LECTURER IN AGRICULTURAL CHEMISTRY (with an honours degree, or its equivalent, and considerable general experience with special experience in animal nutrition)—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh 8 (August 16).

RESEARCH DEMONSTRATOR IN MATHEMATICS—The Registrar, The University, Sheffield (August 16).

ASSISTANT WATER ENGINEER—The Managing Director and Engineer, Lowestoft Water and Gas Company, 163 High Street, Lowestoft (August 20).

RESEARCH ASSISTANT IN PSYCHOLOGY—The Secretary, The University, 38 North Bailey, Durham (August 20).

LECTURER, Grade II (graduate, with a first-class certificate of competency under the Coal Mines Act) IN MINING (Coal), and a LECTURER, Grade II (with a good honours degree, and practical experience in coal preparation) IN COAL TREATMENT—The Secretary, The University, Birmingham 3 (August 23).

RESEARCH ASSISTANTS for work with a small team engaged in research, IN THE DEPARTMENT OF MINING, on the chemical constitution of coal, and a RESEARCH FELLOW IN COAL TREATMENT—The Secretary, The University, Birmingham 3 (August 23).

RESEARCH OFFICER IN THE PLANT AND SOILS LABORATORY, Brisbane, for research on the nutrient requirements of subtropical plants with special reference to pasture legumes—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Ref. No. 3922 (August 23).

ZOOLOGIST (with a first- or second-class honours degree in zoology) for research on the ecology of streams, rivers or lakes—The Director, Freshwater Biological Association, The Ferry House, Far Sawrey, Ambleside, Westmorland (August 31).

ASSISTANT LECTURER IN PHYSICAL CHEMISTRY—The Secretary, University College, Earlsfort Terrace, Dublin (September 1).

BIOCHEMIST (with research experience) to work on problems connected with tissue metabolism and the metabolism of cancer-producing substances—The Secretary, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London, S.W.3 (September 1).

DIRECTOR OF THE IMPERIAL INSTITUTE—The Secretary, Ministry of Education (Establishments General), Curzon Street, London, W.1 (September 1)

ASSISTANT TEACHER (Grade B) IN ZOOLOGY—The Clerk to the Governors, Chelsea Polytechnic, Manresa Road, London, S.W.3 (September 5)

CHEMICAL ENGINEER or CHEMIST, with experience in the design and operation of pilot plants used for obtaining process data, and familiar with instrumentation for automatic control of such plant (Ref. TT/505), a SCIENTIST II—PHYSICIST (with a good honours degree), for laboratory investigations on the briquetting of coal and allied materials (Ref TT/506), SCIENTIST III—PHYSICISTS and ORGANIC CHEMISTS (with a good honours degree), for laboratory investigations on the briquetting of coal and allied materials (Ref. TT/507); a SCIENTIST III, with University or other recognized training in mineral engineering or coal preparation to second-class honours standard (Ref. TT/508); and SCIENTIFIC TECHNOLOGISTS (Grade I), as mechanical and electrical technologists for design, construction and operation of pilot plant connected with the briquetting of coal (Ref. TT/509); at the Central Research Establishment, Stoke Orchard, Cheltenham—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting the appropriate Ref. No. (September 10)

ASSISTANT LECTURER IN ARCHÆOLOGY—The Registrar, University College, Cathays Park, Cardiff (September 13).

CHAIR OF CIVIL ENGINEERING in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 15).

SENIOR RESEARCH FELLOW IN THE DEPARTMENT OF STATISTICS in the Research School of Social Sciences, Australian National University, Canberra—The Administrative Officer in the U.K., Australian National University, 27 Russell Square, London, W.C.1 (September 15).

PHYSICAL CHEMIST, or ORGANIC CHEMIST with special experience of spectroscopy and electrochemistry, as Research Fellow in the Department of Medical Chemistry in the John Curtin School of Medical Research—The Administrative Officer in the U.K., Australian National University, 27 Russell Square, London, W.C.1 (October 31)

ASSISTANT LECTURER (Grade B) IN METALLURGY—The Principal, North Staffordshire Technical College, Stoke-on-Trent

BURSARIES (2) IN THE CHEMISTRY DEPARTMENT of the Imperial College of Science and Technology for research on (*a*) the constitution of molten silicates using viscosity techniques, and (*b*) the fundamental aspects of the sorption of hydrogen by iron—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1

BURSARIES (2) IN THE NUFFIELD RESEARCH GROUP IN EXTRACTIO METALLURGY at the Royal School of Mines, for research on the physica chemistry of high-temperature equilibria involving (*a*) molten silicate and (*b*) molten iron—The Personnel Officer, British Iron and Ste Research Association, 11 Park Lane, London, W.1.

DEMONSTRATOR IN MICRO-BIOLOGY, a DEMONSTRATOR IN AGR CULTURAL CHEMISTRY, and a RESEARCH ASSISTANT IN AGRICULTURA CHEMISTRY, at the School of Agriculture, Sutton Bonington—Th Registrar, The University, Nottingham.

DIRECTOR OF THE BRITISH NON-FERROUS METALS FEDERATION—Peat, Marwick, Mitchell and Co, Lombard House, Great Charl Street, Birmingham 3, endorsed 'Federation Selection Committee'.

EMPIRE RHEUMATISM COUNCIL FELLOWSHIPS—The General Secr tary, Empire Rheumatism Council, Tavistock House (N), Tavisto Square, London, W.C.1.

LECTURER IN PHYSICS—Prof W. H. Watson, Head of the Depar ment of Physics, University of Toronto, Toronto, Canada.

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF AER NAUTICAL ENGINEERING—The Secretary and Registrar, The Universit, Southampton.

RESEARCH ASSISTANT (with a knowledge of electronics and mecha ical physics and, preferably, some research experience) for the develo ment and use of borehole gravimeter—The Department of Geode and Geophysics, Downing Place, Cambridge.

SCIENTIFIC OFFICER (graduate in chemical engineering or fu technology; some practical engineering experience is desirable) f research and development work on coal burning equipment for g turbines—The Assistant Secretary (Ref. A.18), British Coal Utilizatio Research Association, Randalls Road, Leatherhead, Surrey.

SCIENTIFIC OFFICERS (2, honours graduates in physics or enginee ing) IN THE PHYSICS DEPARTMENT, for work on problems in the fiel of (*a*) heat transfer and (*b*) particle mechanics, which includes t properties and behaviour of dust particles—The Assistant Secretar British Coal Utilization Research Association (Ref. A.10), Randal Road, Leatherhead, Surrey.

SOIL SURVEYOR in the Research Division of the Ministry of Agr culture, Sudan—The Sudan Agent in London, Wellington Hous Buckingham Gate, London, S.W.1, quoting 'Soil Surveyor 423'.

SCIENTIFIC FREEDOM AND SECURITY

THE Stevenson Lecture which Dr. J. B. Conant delivered at the London School of Economics and Political Science on March 17 has now been published* under the title "Anglo-American Relations in the Atomic Age". It is important both for some suggestions for co-operation which deserve close consideration by the man of science as well as by the administrator and politician, and as a contribution to Anglo-American understanding. Dr Conant recognizes that Great Britain can help the United States to preserve the conditions of academic integrity and freedom upon which scientific advance largely depends—but only if we attempt to understand conditions in the United States. Equally he recognizes the need for the same attempt at understanding on the part of the United States in regard to what appear to be weaknesses in British security measures and policy.

If Dr. Conant's lecture contributed solely to sufficient understanding to restrain scolding on either side and stimulate counsel instead, he would earn the thanks of men of science generally. His lecture should equally stimulate constructive thought about the real issues—the thinking that is an essential preliminary to the working out of any means of giving effect to the practical suggestions he makes. We are left in no doubt as to the practical difficulties with which international co-operation in such matters as nuclear energy bristles, particularly through the natural reluctance of any nation to enlarge its security risk by divulging secrets of such transcendent importance even to its allies. That difficulty would remain, even if so many scientists everywhere were not genuinely opposed to any restriction of the traditional freedom of publicity in science and if none had communist sympathies.

The heart of Dr. Conant's address lies, in fact in its frank discussion of some of the factors which at present adversely affect Anglo-American relations and of the means by which those factors may be overcome. He does not claim to be unbiased in this discussion, for at the outset he admits that, to his mind, good Anglo-American relations were never more important nor more difficult to achieve than at present. Accurate information and informed interpretation, however, are the right counter to the efforts of those who from private or subversive motives seek to sow discord between the English-speaking nations, and in this address Dr. Conant's sympathies with Great Britain have manifestly not prevented him from approaching his subject on rational lines, or from seeing it in the wider perspective.

Most men of science are only too well aware of the extent to which the position of science in international relations has deteriorated over the past hundred or even fifty years. Not so many appreciate the extent to which, as Dr. Conant also reminds us in this lecture, statesmen and politicians are handicapped from applying the obvious rational measures which a situation demands, through the political pressure exerted by sectional groups looking at only one aspect of the situation. That is true of Great Britain and other countries as well as of the United States.

---

* Anglo-American Relations in the Atomic Age. By Dr. James B. Conant. (Delivered on 17 March 1952 at the London School of Economics and Political Science.) Pp. 42. (London: Oxford University Press, 1952.) 5s. net.

The position is the more dangerous in view of the new situation created by the advent of nuclear weapons. Dr. Conant points out that we are now dealing with the consequences of a new social phenomenon. Until the advent of nuclear weapons, developments in defensive or offensive weapons depended on the special application of the publicly known facts and principles of physics and chemistry. Any new scientific knowledge involved had no revolutionary consequences for the advance of science. The flowering of the whole field of nuclear physics, on the contrary, depended on the expenditure of a large sum of public money, justified in the first instance in terms of the destructive power of a weapon required in a desperate global struggle. Inevitably nuclear physics, thus born of a war-time necessity, was marked from its birth with the secrecy which was anathema to nineteenth-century men of science.

The advance of one whole area of science was thus equated with national security; and Dr. Conant insists that the assumption that science knows no frontier is automatically cancelled and we must face the consequences. We must distinguish sharply between the special position of nuclear science and that of the other fields of physics and chemistry. This is the first step towards preventing the spread of undue secrecy and thereby assisting the progress of science and promoting the welfare of the international community of science.

It is but fair to point out that Government policy in Britain, and probably in the United States also, has on the whole sought to recognize this distinction, however imperfect administration of the policy at times may have been. Another factor to which Dr. Conant directs attention has at times been an embarrassment—the extent to which success in nuclear physics has become a matter of national and political pride. That alone could well account for some of the cruder manifestations of the spirit which has found expression, for example, in the Committee on Un-American Activities or even in some of the investigations under the Loyalty Programme of the United States Government. Dr. Conant does not attempt to justify hysteria, but he appeals for an attempt to understand it; and his lecture gives a welcome reminder that in the universities and elsewhere there has been a much firmer stand against infringements of academic and personal freedom in the United States than could often be gathered from the press.

In this situation Dr. Conant believes that it is impossible to-day, or at any time in the foreseeable future, to have a frank, rational, searching discussion of the industrial uses of nuclear energy. There is no point now in discussing whether the decisions on security regulations in the early days were wise or unwise; but Dr. Conant's own opinion is that misunderstandings and bad feelings between the governments of Canada, Great Britain and the United States might have been avoided by greater frankness at the outset. He thought in 1943, and still thinks, that a treaty should have been drawn up between the three nations dealing with everything even distantly related to nuclear energy.

The chief suggestion he now makes is that an attempt should be made to strike the balance between the demands of security and the demands of justice by a joint commission of the United States and of Great Britain. Such a commission might have to sit behind heavily barred doors; but there is something to be said for Dr. Conant's view that not only is a wise solution more likely to be reached in this way but also that the way would be prepared for a rea partnership in this technical area, comparable with that represented in military matters by the Combined Chiefs of Staff during the Second World War. Even if such a Commission failed to surmount the difficulty in regard to the free exchange of information on nuclear energy noted at the outset, it could scarcely fail to facilitate understanding and co-operation. As Dr. Conant rightly says, the important issue is the future conduct of scientific men, of academic men and of government officials. The more the framework within which these men operate in one country approximates to the framework in which they work in the other, the smoother will be the path of co-operation; and the more nearly that framework is determined on principles which respect the professional loyalties and ideals in which those men are trained, irrespective of nationality, the greater the likelihood of such frameworks being similar. It may not be possible even so to eliminate secrecy or government monopoly; but it should be possible to ensure that they are limited to the minimum consistent with security, and that the area in which the scientific man can work with honest reporting, ful discussion, no political interference and full liberty of investigation is as wide as possible.

In this lecture Dr. Conant dealt primarily with the question of Anglo-American relations and co-operation in relation to this problem of securing a sane balance between freedom and security. It is plain enough that he is aware that co-operation and understanding are also demanded not only across such national frontiers and within the ranks of scientific men themselves, but also between different professional groups—between the scientific man and the administrator, whether Civil servant or academic and between those again and the military authorities and statesmen or politicians. With this aspect indeed, Dr. Conant dealt at some length in a subsequent speech at a luncheon given in his honour in London by the Pilgrims.

The first barrier to be broken down is that between the scientific men of the free nations, and especially between those of Canada, Great Britain and the United States. The grand academic alliance to promote greater understanding between scholars and administrators in the universities of the United States and English-speaking countries of the Commonwealth which he suggested to the Pilgrims could contribute powerfully to that end, as well as place a furthe massive stone in the foundations of good Anglo merican relations. Scientific men to-day depend ery largely on administrative understanding for their eedom of communication and contact with their llows in other lands. It is a matter of governmental r departmental regulation and constraint, and not lways financial restriction, that has frequently revented the free exchange either of information or f visits, and it is well that a man of Dr. Conant's anding should direct attention to the importance f much freer movement of individuals between orth America and Great Britain.

Neither country has been free from examples of liberal restraint on the movement of individual cientific workers, and this plea for closer co-operation etween the administrator and scholar on both sides f the Atlantic has already received a warm welcome. t is already known that a strong American delegation to be invited to the Congress of Universities of he Commonwealth next year in Cambridge ; but the ffective discussion of Dr. Conant's proposal there ill involve much detailed preparatory work, and he careful consideration of administrative as well as inancial obstacles to movement. Recent untoward ncidents like those in which Dr. L. Pauling and Prof. attimore have been concerned may serve a useful urpose in this connexion by indicating some of the rrors to be avoided.

In this connexion it should be noted that Dr. Pauling has now been given a passport to enable him o visit Great Britain and France, and that the Council of the American Association for the Advancement of Science has already expressed its concern over the manner in which measures like the McCarran Act are being administered to prohibit American citizens from going abroad, and citizens of other nations from visiting the United States to interchange knowledge of science which does not affect secrecy. At its meeting in Philadelphia last December, the Council strongly urged a review and modification of the administrative procedures under the McCarran Act so as to modify injustices and the damage to American prestige. It has recently been announced that, because of the delays and embarrassments which foreign men of science experience in attempting to obtain even temporary admission to the United States, the International Congress of Psychology, which was to have been held in New York in 1954, will now be held in Montreal, Canada, where procedures for granting visas appear to be more flexible and realistic. In making this announcement, the American Psychological Association expressed its support of the resolution of the American Association for the Advancement of Science ; the executive secretary of the Association has said that the real objection of scientific men to the McCarran law is that it uses an axe in dealing with a problem that needs a razor-sharp approach.

Meanwhile, Dr. Conant's speech has encouraged all those concerned with educational exchange between the United States and Great Britain, to the value of which the reports of at least two of the 'productivity teams' have recently testified. The Director of Extra Mural Studies at the University of Birmingham estimates that whereas some 1,500 students from the United States have attended summer schools in Britain during recent years, it is doubtful whether as many as a dozen British students have been able to get to comparable schools in the United States in the same period. For this disproportion the dollar exchange position is largely responsible ; but the security regulations of the United States and the visa hurdles which Dr. Conant condemned have also been major obstacles, and there are other minor ones in the questionnaires which applicants for travel grants under the Fulbright Fund are required to complete.

Informal discussion and keen thinking on the part of scientific men as well as of scholars generally and university and Civil service administrators could do much to assist the formulation of practical proposals which the approval of such a congress as that to be held at Cambridge next year would go far to promoting adoption by both governments and universities. It is essential that such discussion and inquiry should proceed with all vigour, even if it may not be necessary to set up a special commission to deal with the whole subject. The Atomic Scientists' Associations in Great Britain and in the United States could well help in this matter, and already the Present Question Conference at Oxford last August* on "Freedom and Responsibility" has assisted in bringing out some of the issues underlying co-operation in this field, while the forthcoming conference on "Conflicts of Loyalties" should further clarify thought.

What has to be realized is that such a matter as the academic alliance which Dr. Conant suggests is not a matter for the universities alone, quite apart from the way in which implementation of any such project may depend upon government action to remove restrictions on movement or even upon government financial support. It is linked up with what is possibly an even more fundamental issue, namely, that of facilitating effective public discussion. Dr. Conant himself referred to the dangerous consequences of the present position, which virtually deprives the public of the accurate and authentic information without which a sound judgment of public policy in this field is impossible, and this is the issue to which, above all, immediate attention is imperative.

Unless that problem is handled wisely, public support is unlikely to be forthcoming for any measures of Anglo-American co-operation in the academic field, still less for any modification of the relations between atomic scientists and the State. Re-examination of institutions and organizations in Britain is imperative even if, as Sir John Cockcroft said at the Present Question Conference, for the moment a working solution has been found which preserves a reasonable degree of freedom for scientific work in nuclear physics. These arrangements need, however, to be scrutinized in a wide context and against the background of the ideas and principles on which a democratic society is based.

---

* Question : a Journal. Edited by H. Westmann. Vol. 4, No. 2 : Freedom and Responsibility.' By Prof. H. D. Lewis, H. J. Blackham, Dr. J. Bronowski and Wells Coates. (Published for the Present Question Conference, Ltd.) Pp. 105–216. (London : Hammond, Hammond and Co., Ltd., 1952.) 2s. 6d.

Dr. J. Bronowski's address to the Seventh Present Question Conference brought out very clearly both the dangers of the present situation and the implications for the scientific man. Vindicating, like Sir John Cockcroft before him, the scientist from the charge of irresponsibility in his scientific work, Dr. Bronowski insists that the great responsibility of the scientific man to-day is to become a teacher to the whole community, and to help his fellow men to understand clearly the implications of the forces which science has released and the changes science is bringing about. Only so is there any hope of society acquiring the wisdom which is required for it to regain control over events, and to choose those directions which tend to good and turn from those that do not. Dr. Conant's addresses should inspire an even wider circle of scientific men and other scholars to turn to the imaginative and constructive thinking out of which will emerge the new institutions of Anglo-American co-operation, whether in science, in the universities or in world affairs generally.

ENTOMOLOGY AND CITRUS FRUIT PRODUCTION

Citrus Entomology in the Middle East

With Special References to Egypt, Iran, Irak, Palestine, Syria, Turkey. By F. S. Bodenheimer. Pp. xii+663. ('s-Gravenhage: Dr. W. Junk, 1951.) n.p.

PROF. F. S. BODENHEIMER'S work is a very thorough compilation of almost all that has been published in the literature, since it covers all the living organisms of the animal kingdom which are related to the now almost universally important problem of citrus fruit production. The part played by insects being by far the most predominant, the author gives an exhaustive account of the results of investigations on the insect pests in the countries surrounding the eastern Mediterranean. In chapters on flies (Diptera), scale insects and thrips, Prof. Bodenheimer fully discusses the ecology of each major pest, selecting not only good and concise descriptions of the species but using also the most recently adopted nomenclature—with keys for the identification of the major groups, as well as of the species. The geographical distribution, a list of the host plants, the seasonal history, the correlation of the development of the insect to temperature and humidity (illustrated by ecoclimograms), threshold of development, thermal constant and the number of generations are given for every important species. Reproduction and productivity, differences between summer and winter eggs, sexual fluctuations, biology of nutrition, fluctuation of populations as a result of change in the nutritional properties of the soil, and numerous other details are discussed and illustrated by a large number of useful tables and graphs. The natural enemies, parasites and predators are studied and supported by judicious conclusions as regards their varying importance based on their biology.

It is to be regretted that Prof. Bodenheimer's book has been considerably retarded owing to the Second World War, for during the past few years the measures of control, particularly those dealing with the most disastrous species of scale insects, have undergone many improvements.

It is unfortunate and regrettable, also, that the list of the most important literature at the end of each chapter does not extend beyond 1946, when the text (Prof. Bodenheimer in his introduction admits that the manuscript of the book was sent to Amsterdam during the early part of the War) is said to have been entirely revised. Moreover, earlier papers such as the valuable piece of research by Dr. A. D. Hanna, on *Ceratitis capitata* Wied. (*Bull. Soc. Fouad I d'Entom.*, 22 (1938), 31 (1947) and 32 (1948)), are not mentioned in the bibliography. The completion of the work in this respect would have considerably enhanced the value of the book. In my opinion, it would have been preferable to combine the bibliography of each chapter at the end of the volume, and an alphabetical index of the names of insects dealt with should have been added.

In spite of these remarks, Prof. Bodenheimer's "Citrus Entomology" is an authoritative and indispensable book, being written with a breadth of view only to be acquired by a truly scientific outlook. I recommend it not only to agricultural research institutes and citrus farmers but also to entomologists the world over.

H. C. EFFLATOUN

PARASITES AND PARASITISM

Parasitic Animals

By Dr. Geoffrey Lapage. (Cambridge Library of Modern Science.) Pp. xxi+351+8 plates. (Cambridge: At the University Press, 1951.) 21s. net.

THIS is not intended to be a text-book of parasitology, but it does contain a considerable amount of factual information concerning a number of forms, mostly those affecting man or domesticated animals. It could only have been written by one who had, like Dr. G. Lapage, devoted years to the study of parasites and parasitism with its manifold practical and theoretical implications. It may be regarded as almost an ecological study of highly specialized animals living in remarkable environments and a discussion of the general principles underlying the relationship. The author makes a plea, that in considering the many aspects of the subject, the student should try to overcome the prejudice resulting from a knowledge of the diseases, pain and loss caused by parasites and should turn to the beauty of the remarkable adaptations they illustrate.

From the method of approach, the arrangement of the contents can be neither that of systematic zoology nor of medical practice. Dr. Lapage has, with success and as the result of the exercise of much thought and ingenuity, produced a logical sequence in the method of presentation. The methods of contact between parasite and host and the ways in which the parasite reaches its resting place are arranged and discussed in a series of examples of increasing complexity. Similarly, the descriptions of life-histories of parasites are not only divided into chapters according to whether one or more than one host is involved, but also within each chapter the life-histories are arranged in series beginning with the most simple and passing by steps to the more and more complex. With this factual material for reference, the author considers the effect of the parasitic mode of life, first upon the parasite itself and secondly upon the host. This naturally leads on to more general questions such as tissue reactions and immunity, and other aspects of the host–parasite elationship. There are but few slips in the book; ut some readers will doubtless consider that the liscussion starting on p. 14 as to whether the fœtus f the mammal is to be regarded as a parasite involves tretching the meaning of the word parasite beyond egitimate biological limits. Indeed, it runs against he grouping of animal associations set out on p. 2, vhere parasites are placed in associations of animals belonging to "different zoological species".

This, however, is a minor point in a most interesting, readable and very useful book. It will appeal o specialists and general zoologists alike, and certainly should be read by all students whose courses nclude a consideration of animal parasitism. Even he lay reader will be able to follow its clear style vithout too much difficulty and find in it much that s of interest and thought-provoking.

ELECTRICAL BREAKDOWN OF SOLIDS

Dielectric Breakdown of Solids

By S. Whitehead. (Monographs on the Physics and Chemistry of Materials.) Pp. xv+272+18 plates. Oxford: Clarendon Press; London: Oxford University Press, 1951.) 25s. net.

ONE may often read of the need for greater interest, in Britain, in the applied sciences and for a more widespread appreciation of their value in education and in industry. Indeed, it is sometimes almost possible to detect, even in authoritative articles, the reiterated outline of a standard complaint. There is, however, little doubt that more attention should be paid, primarily in universities, o applied physics, for example, and the well-known Oxford series of "Monographs on the Physics and Chemistry of Materials" is contributing notably to that end.

The present book, by Dr. S. Whitehead, director of research of the Electrical Research Association, is one of the latest additions to the aforementioned eries, and covers as fully as possible in 272 pages he important subject of electrical breakdown in olids. This is apparently the only modern book of ts kind and follows an earlier one written by the ame author some twenty years ago.

The purpose of the book is to review recent fundamental work in a form suitable for physicists working n university, government or industrial laboratories. t will probably be little used at the present time by undergraduate students in most universities; but esearch students and graduates in general, working on the solid state, will find it of great value.

The author is an outstanding authority on his ubject and, with his colleagues in the Electrical Research Association, has been responsible for many dvances, especially in the study of the effects of mall voids in solid insulation. It is therefore not urprising to find in the book a masterly, but necesarily condensed, treatment of the subject. The hapters deal with intrinsic breakdown, including a ull treatment of the theory of breakdown in simple rystals, which is one of the most fundamental parts f the book; thermal breakdown; breakdown aused by discharges, external or internal to the solid dielectric; electrochemical deterioration; and, finally, dielectric breakdown in technical practice. It is, perhaps, surprising that more space was not evoted to surface sparkover, in view of its great technical importance, even though this is not strictly a problem in breakdown of solids and is controlled greatly by the nature of the electrodes, which diminishes its attraction as a basic general problem. The description of the effects of internal discharges in dielectrics is particularly comprehensive. It seems unfortunate that, having achieved the impossible once, Dr. Whitehead should not have achieved it again by including even one or two chapters on breakdown in liquids.

The book has exceptional value in many respects, but perhaps especially in directing attention repeatedly to the lack of experimental data obtained in controlled and simplified conditions. This applies even to the relatively simple case of electrical breakdown in ionic crystals, and to the study of thin films, where the work of a very few investigators stands out. It is remarkable, as Dr. Whitehead's book so clearly shows, that such an important subject as the electrical breakdown of solids has attracted, with a few notable exceptions, such a small number of research workers. This excellent work should do much to stimulate others.

STATISTICS AND THE CHEMIST

Statistical Methods for Chemists

By W. J. Youden. (Wiley Publications in Statistics.) Pp. x+126. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1951.) 24s. net.

IN this short book, chemists are shown not only how to use statistical analysis but also why to use it and how to plan investigations so that numerical observations will be made to the best advantage. Dr. W. J. Youden writes as one of the few chemists who have studied and practised modern techniques of statistics: his book is full of the wisdom that comes from long experience of his subject-matter.

The book is elementary and well suited for a reader without previous knowledge of statistics. Theory and proofs are almost entirely absent, yet the logical basis of the methods discussed is always clear. The first chapter displays the need for proper statistical treatment of chemical data by showing—a favourite theme of mine—that often the man who refuses to use statistics is in reality using inefficient statistical methods when better ones are readily available. Subsequent chapters relate to the various concepts that enter into analysis of variance, regression analysis, and experimental design, together with short sections on sampling. In the main, the presentation is of the kind familiar in texts of biological statistics; but it takes on a distinctive character because the illustrations are drawn from chemical investigations. Dr. Youden rightly insists that a proper understanding of the functions of statistics in chemistry can be attained only by study of practical problems; he therefore puts before his readers a fine and varied selection of experimental data, largely from pieces of research with which he has been personally concerned. Especially valuable are the explanations of experimental designs and their uses. Dr. Youden gives an excellent introduction to incomplete blocks and complete and incomplete replications of factorial schemes; but the emphasis is on general principles rather than details of interpretation, and the chemist concerned with elaborate experiments would probably need further guidance from another book.

Perhaps the most surprising point is the complete absence of any discussion of discrete variation: neither χ^2 nor the binomial distribution is mentioned. The discussion of sampling is rather inadequate, and no mention is made of quality control, a branch of applied statistics that would seem to be of special interest to chemists. The very brief chapter on regression would be improved by some recognition of the existence of multiple regression methods. Such flaws are inevitable in so short a book, but a study of what Dr. Youden has said should encourage many chemists not only to put his simpler procedures to immediate use but also to read more widely in other text-books of applied statistics. D. J. Finney

SURVEY OF CANCER IN LONDON DURING 1938-39

British Empire Cancer Campaign

A Survey of Cancer in London: Report of the Clinical Cancer Research Committee. By Dr. W. L. Harnett. Pp. vi+834. (London: British Empire Cancer Campaign, 1952.) 45*s*.

Between 1936 and 1938 the Clinical Cancer Research Committee of the British Empire Cancer Campaign designed thirty-one detailed case-sheets, applicable to patients suffering from cancer in the various regions of the body, which were distributed to all the voluntary and London County Council hospitals and most of the special hospitals in the County of London. 15,200 patients were registered from April 1938 to September 1939, and the data on their case-sheets coded by Colonel W. L. Harnett, the full-time medical secretary and registrar to the Committee. A five-year follow-up was carried out, and only four hundred cases could not be traced. The primary design was to secure accurate information on the efficacy of the various methods of treatment available; but, in addition, much data on other aspects of clinical cancer were obtained. Analyses on half the material were published in the Annual Reports of the British Empire Cancer Campaign. This survey gives the revised findings, both summarized and detailed, in the whole series of patients.

There were sufficient cases for detailed analyses in thirty-four out of the forty-three sites of registered malignancy. Each site is analysed under about thirty headings, which, in addition to types of therapy and follow-up, include age distribution, occupation and social class, relevant past history, first symptoms, delay in treatment, findings on examination, clinical stages, actuarial estimation of survival after treatment, biopsy reports and causes of death. The number of cases in the commoner cancers is large—breast, 2,152; stomach, 1,405; rectum, 1,390; skin, 1,080; lung, 1,024; colon, 892; cervix uteri, 859; bladder, 423; pharynx, 385; prostate, 383—and their analyses are thereby of great significance.

Comparison of different treatments summarized from the whole data favours radical surgery combined with radiotherapy over radical surgery, while the latter was better than radiotherapy alone. However, the results varied according to the site, stage, age and selection of the patients. In cancer of the breast, for example, post-radical mastectomy irradiation slightly improved the long-term results in clinical stage III*b* but not in any other stage. Again and again throughout the survey, the already long-established fact is accentuated by the tables that early cases of cancer do well with any orthodox treatment but that, once the lymph nodes are involved, the number of five-year survivors is considerably reduced, whatever the treatment. The totals of all sites variously treated, analysed according to stages, showed a five-year survival-rate of 38·7 per cent in stage I, 20·0 in stage II, 13·2 in stage III and 1·5 in stage IV. About one-third of all cases proved to be clinical stage I on admission to hospital.

The interval from first symptom to medical consultation varied greatly with the site. It was less than three months in 53·1 per cent of the 12,277 records in which the data were available, and more than six months in 20·8 per cent. Of the 12,125 patients who consulted a medical practitioner, 68 per cent were referred to hospital at once. The five-year survival-rate for all methods of treatment was 19·22 per cent of the 14,182 patients with primary cancer. In his introduction to the "Survey", Sir Heneage Ogilvie says that this figure would have been raised to 38·7 per cent had all patients come to hospital while the disease was still in stage I. This is an indirect plea for earlier diagnosis and treatment, laudable but perhaps over-optimistic with regard to the benefit which might ensue, since rapidly growing and spreading tumours constitute a fair proportion of most groups of malignancies. It is a pity that the Research Committee did not look into this matter by an attempt to correlate the stage with the length of history. Such a correlation might establish how many advanced cancers are in that state because of prolonged delay in diagnosis and how many are due to the presence of a rapidly spreading tumour. In a number of sites the survival-rate has been correlated with duration of symptoms and, interestingly enough, rarely shows any statistically significant difference between patients who came under treatment within the first six months and those who delayed longer.

Analyses of social class agree with the Registrar-General's conclusions from mortality figures that the poorer groups are more liable to cancer of the tonsil, pharynx, lip, mouth, tongue, œsophagus and skin. The significance of the findings in the patients' relevant past history, such as incidence of unsatisfactory dental conditions, heavy smoking or excessive alcohol consumption in relation to cancer of the mouth, pharynx and larynx; pre-existing goitre with cancer of the thyroid; gall stones with cancer of the gall bladder and a number of other conditions cannot be judged because of the absence of data on their incidence in a control non-cancerous population selected at the same time. A previous history of tuberculosis, pneumonia and influenza was recorded in the cancer of lung series; it was unfortunate that smoking habits were not recorded in these patients.

This survey is an example of a research approach which is likely to prove every whit as important as the laboratory one, and which, if the right questions are asked, might be even more fruitful. As it stands, we see the state of cancer at the hospitals of Greater London in the year preceding the outbreak of the Second World War, preserved for posterity—a base-line for studies on changing incidence, diagnosis, clinical manifestations and treatment. Everyone interested in malignant disease will be deeply indebted to the British Empire Cancer Campaign for its production of this unique and monumental survey of cancer in London. I. Doniach

THE OAK RIDGE 86-INCH CYCLOTRON

By Dr. ROBERT S. LIVINGSTON
Oak Ridge National Laboratory, Tennessee

THE construction of an 86-in. high-current proton cyclotron of the fixed-frequency type was started at Oak Ridge in August 1949. Design and fabrication of the machine was completed by the staff of the Oak Ridge National Laboratory with the assistance of other personnel and facilities of the Carbide and Carbon Chemicals Co. in almost exactly one year. On November 11, 1950, the first beam was obtained. The cyclotron now produces an internal beam in excess of one milliampere of protons at 24 MeV. At this energy the relativistic increase in mass is 2·6 per cent.

The maximum particle energy which a fixed-frequency cyclotron can produce is a function, of course, of the available dee voltage. When proper account is taken of the rate and shape of magnetic field fall-off, ion 'phase grouping', relativistic mass increase, and electric and magnetic focusing, the threshold voltage for any given energy can be calculated reliably[1].

The major specifications of the 86-in. cyclotron are as follows: diameter of pole face, 86 in.; maximum beam radius, 33 in; magnetic field strength, 9,000 oersteds; resonance frequency, 13·4 megacycles per sec.; peak dee-to-dee potential, 300 kV. min., 500 kV. max.; dee-to-dee gap, 4 in.; dee width, 8 in.

The cyclotron is unique in that the orientation of the magnetic field is at right angles to that in conventional machines (Fig. 1). The dees are suspended vertically and can be lowered into the vacuum tank by a crane. The magnet, vacuum system, oscillator and testing console are in a room 28 ft. × 34 ft. This room is entirely surrounded by a shielding wall of ordinary concrete 5 ft. thick. Three walls are solid and the fourth is of blocks laid without mortar. The overhead portion of the shielding is composed of removable blocks which provide convenient access when modifications are required. An operating console, 400 ft. away from the cyclotron, provides for additional protection from radiation while the machine is operating at high level.

The U-shaped magnet yoke for the cyclotron is 40 in. × 62 in. in cross-section and weighs 250 tons. The vacuum system consists of three 20-in. oil-diffusion pumps, each equipped with an 8-in. booster pump, exhausting to a common header and backed by a 15-h.p. mechanical pump. The total pumping speed of the system is 15,000 litres per sec. at 0·03 micron.

The oscillator is of the grounded-grid self-excited type using a single Federal 134 tube. This tube is rated at 400-kW. input and 150-kW. plate dissipation. Several systems were investigated for overcoming the well-known 'ion loading' phenomenon, which makes it very difficult to obtain satisfactory starting conditions with the self-excited oscillator.

A dee-bias system using a negative 1,000-V. potential on the dees is the most successful method tried for control of ion loading. In investigation of other methods, the use of a pre-exciter oscillator was tested, and a charged-grid system made of copper tubes was suspended between the dees and the ground plane. It was found that the biasing system produces

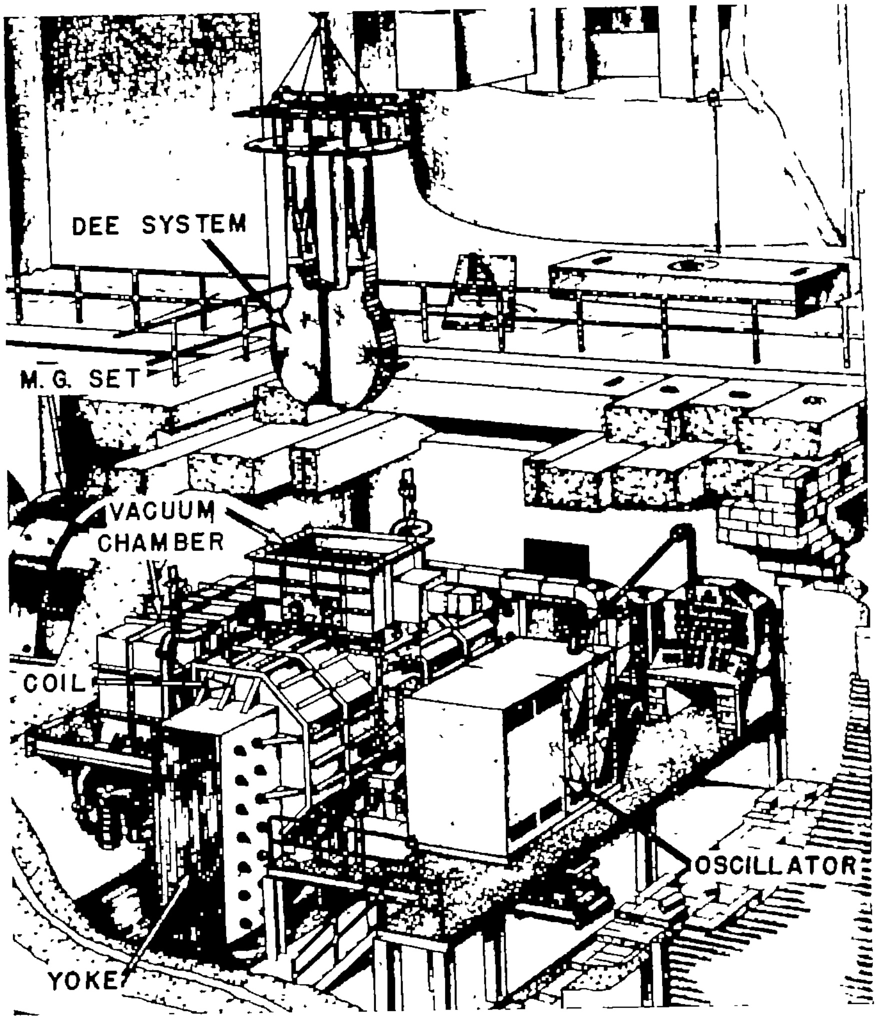

Fig. 1. Artist's sketch of the 86-in. cyclotron installation showing motor-generator, vacuum system, magnet, dee assembly, oscillator cabinet, and shielding

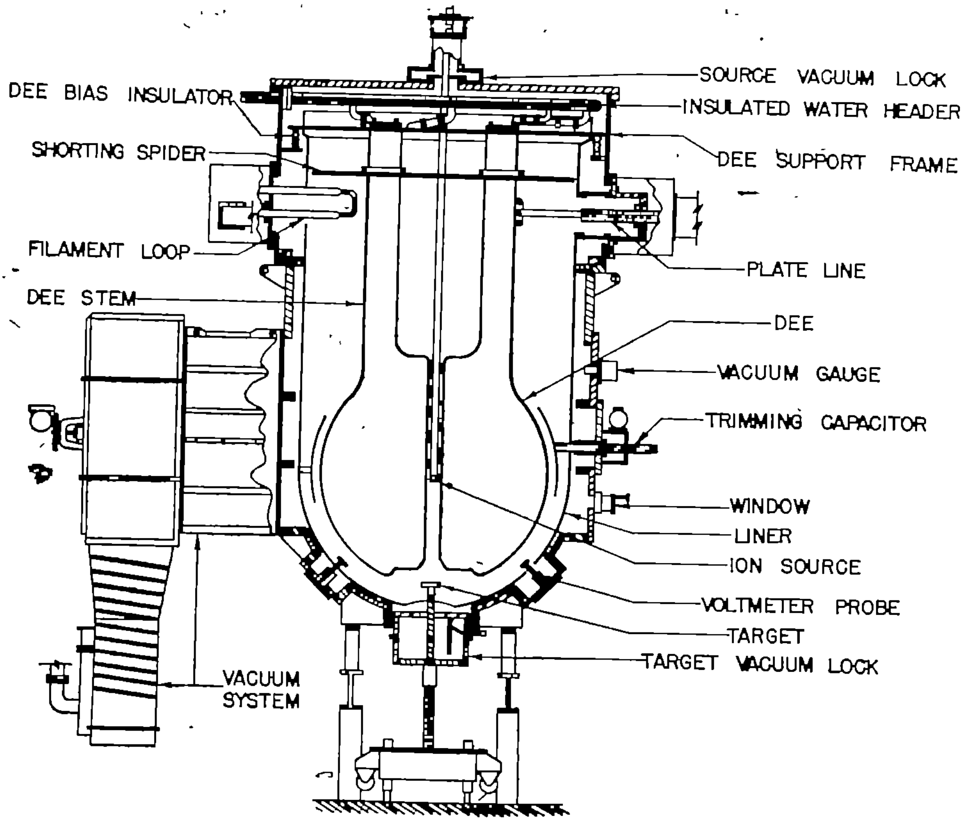

Fig. 2. Diagram of the resonant dee system. The ion source and the target are inserted through vacuum locks, from above and below respectively

the most dependable operation and permits a much higher dee voltage than the grid system. At present the voltage ranges between 280 kV. and 400 kV. dee to dee. Highly stable oscillator operation is achieved, and it is of interest to note that the oscillator may be turned on safely at full power.

The resonant system of the cyclotron is illustrated in Fig. 2. The copper-plated stainless steel framework which supports the dees rests upon, and is insulated by, four stand-off type cylinders of Alsimag 222 (American Lava Co.). A 500 μμF. capacitance is inserted in series with the plate transmission line, at the tube end, to prevent shorting of the D.C. bias. It was not found necessary to add any condensers between the 'r.f.-shorting-spider' and the liner; but great care is taken to balance the capacity of the dees exactly in order to minimize the 'unbalanced' current which flows between the dees and the liner. Heavy silver-plated copper clamps, with water cooling, successfully carry the very large radio-frequency currents (~ 5,000 amp.) at the voltage node of the resonant quarter-wave dee system.

In this cyclotron it was desired to use large circulating currents without making the dees intensely radioactive. To accomplish this, the dees are completely lined with a layer of graphite, so that any stray protons are prevented from impinging directly on the copper. The leading edges of the dees are also of graphite. It was gratifying to observe that after one million μampere-hours of operation, the dees could be approached quite safely within a few hours for carrying out alterations. It has been observed that the limiting activities near the cyclotron, exclusive of the targets, are those due to silver-110 (270 days) and iron-59 (43 days), both of which are induced by neutrons. In the fabrication of future dees, an attempt will be made to eliminate silver (from brazing alloys) completely.

A simplified technique has been worked out for the fabrication of components of the resonant radio-frequency system, where large amounts of heat due to either the radio-frequency heating or to impingement of the beam must be removed. This has proved highly satisfactory for such structures as the dees and liner. Water tubes of 0·875-in. outside diameter, flattened to increase the area of contact, are furnace-brazed to sheets of copper 0·090–0·125 in. in thickness. 'Heliarc' welding is used in joining sheets where high conductivity is desired, and vacuum-tight construction is not required. Continuous lengths of tubing are used wherever feasible.

In order to establish the energy of the beam by a measurement not dependent on the geometry of the cyclotron, three different methods have been used. The first of these consists of the bombardment of stacks of thin foils such that the depth of activity may be traced for a particular reaction. The best results by this method have been obtained with copper foils. The reactions used were ^{63}Cu(p,n)^{63}Zn and ^{63}Cu(p,2n)^{62}Zn, having extrapolated activation thresholds of 4·5 and 14·5 MeV., respectively. Some work has also been done with carbon foils by tracing the activation as a function of depth for the ^{12}C(p,pn)^{11}C reaction, which has an extrapolated threshold of 18·7 MeV. In the second method, the energy has been measured by allowing the beam to impinge upon a photographic plate after passing through a stepped aluminium absorber. The third nethod is by the use of a 'burn-out target' consisting f a series of separated lead foils placed across the path f the beam. The curvature of the 'burn-out' pattern roduced by the circulating beam and the known ntensity of the magnetic field give a maximum value f the energy.

These methods of measurement are all in subtantial agreement and indicate that the energy of he beam can be as much as perhaps 10 per cent ugher or lower than that calculated from the cycloron geometry. The variations in energy are dependent rimarily on the position of the ion source.

A particular problem with this cyclotron is the esign of internal targets and the facilities for nstalling and removing these targets from the yclotron. The target-mounting assembly is perlanently arranged on a stainless steel carriage. Hydraulic cylinders are incorporated in the carriage or actuating the target dolly by remote control and or holding the target face-plate against the vacuum ock. The carriage contains a separate motor-driven crew mechanism for raising or lowering the target o the desired radius. For rotating targets, provision as also been made for an auxiliary motor drive.

While many types of targets have been designed, wo are described to illustrate the types of arrangenents which have proved practical. In the first type, he beam passes through a 0·015-in. aluminium window and into the target directly behind the window. Cooling water circulates in contact with the arget, which is held in place by a spring clip. This a convenient system for irradiating metallic targets hen only a few microampere-hours are needed. eams greater than 100 μamp. have been used withut damage to the aluminium windows.

When larger irradiations are desired, it has been ound convenient to place a target at a small angle the incident beam (2–5°) and to make the target s large as possible. Aluminium targets 6 in. × 10 in. ave safely withstood more than 30 kW. of beam, easured calorimetrically. It should be noted that is necessary to have high-velocity water flowing in ne cooling circuit in such a target in order to obtain ifficient heat transfer. The induced activities at rge beam currents are extremely high. A zinc target ombarded for an hour at 400 μamp. gives 50 R./hr. 1 m. On a beryllium target, one neutron is released r approximately every fifty incident protons. To cilitate quick and easy removal of such 'hot' rgets, an arrangement has been designed such that quarter turn of a lever permits removal of the rget with a pair of long tongs or with remotely perated handling equipment.

ARIABLE STARS AND GALACTIC STRUCTURE*

By CECILIA PAYNE-GAPOSCHKIN

THE intrinsic variable stars are the stars whose changes of brightness, temperature and spectrum e the results of physical changes of a single object, contrast to the geometrical variables, which show e effects of periodic eclipses of a close stellar pair. trinsic variables may be roughly divided between the pulsating variables (which undergo periodic or quasi-periodic changes governed by their physical properties) and explosive variables (which undergo changes that are more nearly explosions, and are, at the most, cyclic in nature).

Variable Stars

The pulsating variables embrace the classical Cepheids (periods of a day to fifty days or more); the *RR* Lyræ stars (periods less than a day), the yellow semi-regular variables (including the *W* Virginis stars, the *RV* Tauri stars, and the stars such as *SX* Herculis, with periods that range from about twenty to more than a hundred days), and the long-period variables with large ranges, and periods from rather less than a hundred to almost a thousand days. These divisions are not arbitrary, but are borne out by the physical nature of the stars in each group, as well as by their distribution and motion. Although all seem to undergo some type of pulsation, little progress has been made in understanding the details, or in analysing the complex interrelationships that exist between brightness, temperature, spectrum and radial motion of the surface.

The explosive variables include the supernovæ, the classical novæ, recurrent novæ, and dwarf novæ (*U* Geminorum and *Z* Camelopardalis stars). They are listed in descending order of maximal brightness; with the exception of the supernovæ, their outbursts are probably cyclic, those that reach the smallest luminosity at maximum having the shortest cycles. For these stars also, the abrupt changes of brightness, and the associated complex changes of spectrum, temperature and surface velocity are at present understood only in the most general way.

The intrinsic variables, despite the difficult physical problems that they present, can be studied fruitfully from another point of view. All are stars above the average in luminosity, and for each class the absolute magnitudes are fairly well determined. Therefore they can be located within the galaxy when correct allowance has been made for obscuration (a problem at present only approximately soluble), and the structure of the galactic system can be studied by their means better than in any other way.

Galactic Structure

The distribution of any group of stars within a galaxy may be regarded as the instantaneous result of the motions of the stars concerned. We shall find that the intrinsic variables fall into definite groups, not only on the basis of physical behaviour and of distribution, but also of motion. They form part of the general picture of the complex structure of our galaxy, which we may regard as the outcome of the motion of stars, nebulosity, and dust, in orbits of a variety of sizes, shapes and inclinations about the centre of the system.

A spiral galaxy, such as we may suppose our own system to be, has a complex structure. The main part of the light comes from a somewhat flattened spheroidal mass of stars, which also contains most of the mass. The spiral arms, superficially conspicuous in spirals such as Messier 31 in Andromeda, contribute perhaps ten per cent of the light, and are confined to a comparatively thin central layer, which also contains the dust and gas. This picture, which has emerged from the study of the nearer spiral galaxies, seems to be applicable to our own system, though in the latter the structure is more difficult to trace; this is because the sun happens to lie at present almost in the central plane, so that we encounter the full obscuring effect of the layer of dust.

---

* Synopsis of three lectures given in the University of London on y 5, 7 and 8.

Stellar Populations

Within our own galaxy, the motions of the stars give a clue to the structure of which they form part. Stars characteristic of arms move in nearly circular orbits of low inclination; stars of the substratum may move in orbits of high inclination, and also of high eccentricity. Therefore their motion relative to the sun (which shares the motion of stars associated with the arms) may be considerable, and they embrace the 'high-velocity stars', first recognized by Oort. In the notation first suggested by Baade, the stars characteristic of the arms are known as 'population I', those of the substratum as 'population II'. Extreme specimens of population I are the galactic (sometimes called the open) clusters: they are confined to the galactic plane and move in nearly circular orbits. Extreme examples of population II are the globular clusters, which form a nearly spherical system about the galactic centre, and the large dispersion in their radial velocities places them among the high-velocity objects.

The galactic and globular clusters show a profound difference of population. The brightest stars of galactic clusters are the bluest—often blue super-giants of great luminosity—and their members run downwards along the main sequence; such clusters may, however, contain a few red giants. The brightest stars of globular clusters are the reddest, and are never as bright as the brightest blue stars of such galactic clusters as the Double Cluster in Perseus and the Pleiades.

The main population of the globular clusters runs from red to blue towards lower luminosity, and appears (from recent work at Mount Wilson) to converge with the main sequence for stars not much different in brightness from the sun. Globular clusters contain some bluer stars, which tend to form a branch of the colour-luminosity array near absolute magnitude zero; this branch embraces a variety of colours. The *RR* Lyræ stars, which are very numerous in many (though by no means in all) globular clusters, lie on this branch. These two population-patterns are characteristic respectively of stellar populations I and II. It is tempting to see in them a contrast which results from difference of origin, age or history.

Characteristics of Variable Stars

In order to relate the distribution and motion of a group of stars to the structure of our galaxy, we need to know their distances, and therefore their absolute magnitudes. This information is available for five main groups of intrinsic variables.

The *classical Cepheids* are distinguished by concurrent changes of brightness and radial velocity, by the relation between period and minimal spectrum, and by the progression of form of light curve with period (the Hertzsprung relation). They form a distinctive, but probably not a homogeneous, group, for none of the three relations mentioned is unique. The absolute magnitudes tend to be greatest for the Cepheids of longest period (the period-luminosity law, established by Miss Leavitt in the Magellanic Clouds, and assumed to be valid for all classical Cepheids). The Magellanic material establishes the scale of the period-luminosity curve; but the zero point must be established from the motions of comparatively few nearby galactic Cepheids, as has been done by R. E. Wilson. The absolute photographic magnitudes of classical Cepheids, which are thus functions of period, lie between − 1, for the shortest periods, to about − 4·5, for the longest. Classical Cepheids include the most luminous of intrinsic variables.

The luminosities of the *long-period variables* must be derived entirely from the motions of galactic members of the group. They are found by Merrill and R. E. Wilson to range from about + 1 for the longest periods to about − 2 for the shortest. The relation is less simple than for the classical Cepheids, since the long-period variables of shortest period tend to be high-velocity stars, and the velocities appear to bridge the gap separating populations II and I between the shortest and the longest periods. Studies of luminosity that are based on proper motions require modification for high-velocity stars, and therefore the luminosities of individual long-period variables cannot be confidently inferred from period alone. These variables cannot, moreover, be shown to consist of two distinct groups, for the gradation of motion (and distribution) is continuous, and there seems to be no relation between motion and such physical properties as can be inferred from spectra. Our knowledge of the distribution and motions of the long-period variables is thus necessarily less definite than for the classical Cepheids.

The *red semi-regular variables*, with very few exceptions, share the motion that is typical of population I; their absolute magnitudes are shown, by the studies of R. H. Wilson, Joy and Keenan, to be in the neighbourhood of 0 or − 1, except for the readily recognizable super-giants, such as Antares and *AD* Persei.

The luminosities of the *yellow semi-regular variables*, which include the *W* Virginis stars, the *RV* Tauri stars, and such stars as *SX* Herculis, have been established by Joy's studies of variables in globular clusters; they range from −1 to −3. These stars are distinctive in light curve and in spectrum; in particular, the *W* Virginis stars can be readily distinguished from classical Cepheids of similar period by their striking departure from the Hertzsprung relation.

The *RR Lyræ stars*, distinctive in period and in form of light curve, have been shown by a number of investigators to have an absolute magnitude near zero. They are, moreover, all sensibly of the same luminosity. As they are high-velocity stars, the absolute magnitudes of the galactic members, on which the determination necessarily depends as present, must be evaluated on the basis of radia velocity only.

Distribution of Variable Stars

Although only a fraction of the total of galacti variable stars has been discovered, their apparen distribution, in conjunction with our knowledge o their luminosities, and approximate corrections fo obscuration, permits us to draw certain conclusions about true distribution. From the fragmentary material available, it is only legitimate to arrange the distributional parameters in order. *Horisonta gradient* expresses the rate at which stars of a given type increase in numbers along a galactic radius from the centre outward. *Vertical gradient* expresses the rate at which they fall off above and below the galactic plane.

The horizontal gradient is greatest for the *RR* yræ stars, and almost as large for the long-period ariables of shortest period. For variable stars of ther types it is too indefinite to be evaluated. The ertical gradient is smallest for the globular clusters xtreme population II); then follow, in order, the *R* Lyræ stars, the *W* Virginis stars, the *RV* Tauri tars, the long-period variables of short period, the ng-period variables of long period, the semi-regular d stars, the classical Cepheids, and finally the alactic clusters (extreme population I). From this follows that the globular clusters form the most pherical subsystem of the galaxy, and the succeeding bjects constitute more and more flattened subystems, until we reach the classical Cepheids and alactic clusters, which are practically confined to a hin layer near the galactic plane.

The novæ appear to form a system which is otably concentrated towards the galactic centre, eing not so closely confined to the galactic plane as he classical Cepheids, but more flattened than the ystem of *RR* Lyræ stars. The planetary nebulæ have een shown by Minkowski to be concentrated in the irection of the galactic centre, but, until their istances are measured, neither the horizontal nor he vertical gradient can be evaluated. Their distribution suggests that of the novæ.

Motions of Variable Stars

The motions of the various types of intrinsic ariables are even less completely known than the istributions. The Bottlinger diagram (despite its rude implication of Keplerian motion, and the evere limitations imposed by selection) provides a ethod of arranging the motions in definite order. Vhen the observed motions of variable stars are nserted in a Bottlinger diagram, one can determine ne distributions of eccentricity and semi-major axis f the instantaneous orbits. In order of decreasing edian eccentricity, we find the *RR* Lyræ stars, the ng-period variables of short period, the red semiegular variables, the long-period variables of long eriod, and finally the Cepheids with essentially rcular orbits. The median semi-major axes do not iffer sensibly except for the *RR* Lyræ stars, which ave the smallest.

If we accept the crude assumption of Keplerian otion (probably approximately valid in our own parsely populated neighbourhood), we can calculate ne average perigalactic distances for the stars of arious types: the smallest are those of the *RR* yræ stars, followed in order by the long-period ariables of short period, the red semi-regular ariables, the long-period variables of long period, nd the classical Cepheids. Unfortunately, our nowledge of the motions of the yellow semi-regular ariables is at present too scanty for application ere; they do, however, contain a considerable roportion of high-velocity stars (as shown by Joy's udy of radial velocities), and would probably fall etween the *RR* Lyræ stars and the long-period ariables of short period.

Galactic Structure and Variable Stars

The distribution of variable stars shows a conuous graduation from the nearly spherical subystem of the *RR* Lyræ stars (which approaches that the globular clusters in form, if not in extent) to ne highly flattened system of the classical Cepheids (which approaches that of the galactic clusters). The galactic clusters themselves contain a considerable proportion of the highly luminous hot stars, the more so if we include in our conception the looser associations of hot stars which have long been known to be concentrated in the galactic plane. Variable stars, then, strengthen the conception of a galaxy built of a number of concentric subsystems, flattened to various extents.

When we seek among the variable stars for evidences of structure within the central layer of the galaxy, which contains dust, gas and high-luminosity hot stars, we are on less sure ground. Recent studies by W. W. Morgan have suggested the feasibility of tracing actual spiral structure within the central layer by means of the bright nebulosities excited by high-temperature stars. If any intrinsic variables share the spiral structure, we should expect the classical Cepheids to do so. The distribution of these stars in the galactic plane does, indeed, seem to suggest a concentration parallel to the spiral structure suggested by the bright nebulosity, but the features are extremely broad and indefinite.

Even if we allow for the possible dispersion about the period-luminosity curve that seems to follow from the Magellanic material, it is difficult to believe that the galactic Cepheids are confined to narrow, armlike regions. Rather they seem to be spread into a sheet, which perhaps shows a tendency to concentration in spiral lanes. The few Cepheids that were found by Hubble in Messier 31 seem also to be broadly scattered, rather than to be concentrated in narrow, arm-like regions such as Baade has recently photographed by means of the bright nebulosities. The classical Cepheids, therefore, while definitely affiliated with population I, are not such extreme members of it as the high-luminosity hot stars which are the brightest members of many galactic clusters.

NEWS and VIEWS

National Chemical Laboratory of India: Prof. G. I. Finch, M.B.E., F.R.S.

Prof. G. I. Finch has been appointed by the Council of Scientific and Industrial Research, India, as director of the National Chemical Laboratory of India, Poona, in succession to Prof. J. W. McBain, who has recently retired. Prof. Finch has had a long and distinguished academic career. After studying physiology under Charles Richet in Paris, he went to Zurich to read chemistry and physics under Treadwell, Willstätter, Bredig, Lunge, Berl, Weiss and Einstein. On graduating, he served as assistant to Bredig and later under du Parc at the University of Geneva. This long and varied course of stimulating study, combined with frequent vacation work, laid the basis for the deep interest which Finch has maintained throughout his career in the industrial application of scientific knowledge and advances. After serving as assistant research chemist under the late Sir Robert Robertson at the Royal Arsenal in Woolwich, Finch, early in 1913, joined the late Prof. W. A. Bone as his demonstrator in the newly formed Fuel Department at the Imperial College, where, except for absences during the two World Wars and with the 1922 Mount Everest Expedition, he has remained as lecturer, assistant professor in electro-chemistry and (since 1936) professor of applied physical chemistry for nearly thirty-nine years.

As might be expected from his comprehensive early training, Finch's researches have ranged over many fields. Under Bone's influence he first turned towards the efficient use of coal and its by-products, safety in mines and catalytic combustion, and these interests were reflected in his early researches on the ignition and combustion of gases. His recognition of the vital part played by surface structure in heterogeneous catalysis led him to the study of surfaces by electron diffraction, a technique with which his name is internationally associated, and which he has applied to the examination of a wide range of chemical and physical problems. This work was recognized by his election to the Francqui chair in the University of Brussels during 1937–38 and, in conjunction with his important fundamental work on the electrical ignition of gases, by the award of the Hughes Medal of the Royal Society in 1944. In his new sphere Prof. Finch will find ample opportunity to pursue his many interests in the field of applied chemistry to the advantage of Indian economy.

Institute of Welding: New President and Vice-President

At the annual general meeting of the Institute of Welding, held at the Institution of Civil Engineers on July 22, Mr. A. Robert Jenkins and Mr. H. B. Fergusson were installed as president and vice-president, respectively, for the year 1952–53. Mr. Jenkins is a graduate in mechanical engineering of the University of Sheffield, and after his apprenticeship entered in 1931 his family business of Robert Jenkins and Co., Ltd., of Rotherham. He is now deputy managing director of the firm and also, since 1946, works director, in which position he is responsible for the whole of the production and technical side of a works now producing about a thousand tons of fabricated products a month. Mr. Jenkins has travelled widely, visiting factories in Sweden, Germany and the United States, and was a member of the Specialist Productivity Team on Welding which visited the United States in 1950. Mr. Fergusson was educated as a mining engineer in Freiberg, Germany, and later had a distinguished career in railway construction and other engineering projects in Canada, Spain, South America and Russia, where during the First World War he was in charge of 750 Canadian railway-men building the Murmansk Railway. For the past fifteen years he has been a director of G. A. Harvey and Co. (London), Ltd.

University College of the West Indies: New Principal

Dr. W. W. Grave, registrary of the University of Cambridge since 1943, has been appointed principal of the University College of the West Indies in succession to Sir Thomas Taylor, who has been elected principal of the University College of the South-West of England, Exeter. He is expected to take up his new duties in 1953. Dr. Grave was educated at King Edward VII School, King's Lynn, and at Emmanuel College, Cambridge. He took his B.A. degree in 1924, after being placed in the first class in both parts of the Modern and Medieval Languages Tripos. He was elected Fellow of Emmanuel College in 1926, and was a tutor of the College during 1936–40. In 1936 he was appointed University lecturer in Spanish, and during 1940–43 was a temporary administrative officer in the Ministry of Labour and National Service.

British Standards Institution: New Appointment

At the annual general meeting of the Britis Standards Institution, held at 24 Victoria Stree London, S.W.1, on July 23, it was announced tha Mr. John Ryan had been elected chairman by th General Council in succession to Sir Roger Duncalf who has completed his three-year term of office. A the meeting Viscount Waverley was re-electe president of the Institution for the third year, an Sir Roger Duncalfe vice-president. Sir Roger, wh has been chairman of the Institution during thre years of most rapid growth, is widely known i industry as the chairman of British Glues an Chemicals, Ltd. He is also a past chairman an past president, and now a vice-president, of th Association of British Chemical Manufacturers, an a vice-president of the Federation of British Industries. Previously in the Institution he had bee chairman of the Adhesives Industry Standards Committee and of the Finance Committee. Mr. J. Rya is vice-chairman of the Metal Box Co., Ltd., and he for many years played a leading part in the standardization policies implemented through the Britis Standards Institution by the packaging industry He was appointed chairman of the Packagin Standards Committee on its formation in 1941 an was intimately concerned with the development o the war-time Packaging Code, which resulted no only in great economies during the Second Worl War but has also been of much importance to Britis industry in peace-time, particularly in the expor field. Since 1948 he has been chairman of th Institution's Finance Committee. Widely know as an expert in company finance and administration, Mr. Ryan is a member of council and Fellow of the Royal Statistical Society and hold senior offices in many trade organizations and th British Institute of Management.

University Degrees in Nutrition and Househol Science

Courses for the two new degrees of B.Sc. (Nutr tion) and B.Sc. (Household Science) will start a King's College of Household and Social Scienc (University of London) in October 1953. The degrees will replace the present degree of B.S (Household and Social Science). The B.Sc. (Nutritio degree is designed to make available for the fir time in Britain an integrated course in this relativel new science. The course will include a study of foo production, taking into account such factors climate, soil, pests and diseases; food processing an preparation; food chemistry; food consumption an its economic and social deficiency. It will be a val able preparation for those who intend to go in f nutritional research, to become dietitians, or to tak up advisory and research posts with international national organizations, with local authorities an other bodies which are increasingly undertakin work on the problems of nutrition. The cour for the degree of B.Sc. (Household Science) will comprise work in the practical and scientific aspects the preparation of food, the chemistry of food-stuff the principles of institutional management and hou planning; and other subjects which come under th general title of household science, with a backgroun of chemistry, physiology and other allied science It is designed to meet the same sort of requiremen as the present course for the degree of B.Sc. (Hous hold and Social Science) and will be specially suitab or those who intend to make their careers in the eaching of domestic science, in institutional management, and in various branches of scientific research.

Sub-Fossil Hekla Pumice from Denmark

PROF. A. NOE-NYGAARD has written a paper on the "Sub-Fossil Hekla Pumice from Denmark" *Medd. Dansk Geol. For.*, 12, Heft 1, 35; 1951), in which is reproduced a photograph showing immense fields of drifting pumice in the sea off the Westmann Islands only a few days after the beginning of the Hekla eruption of March 1947. Hekla and several other volcanoes in the south of Iceland have emitted many flows of a uniform type of oversaturated glassy basalt; but investigations during the past decade have proved that intermediate to acid rocks are also represented to a considerable extent in the Hekla volcanic area, and that lavas and ashes of like composition, especially andesitic pumice, were ejected during the eruption of 1947. Prof. Noe-Nygaard has investigated the finds of sub-fossil pumice which have been made at three places in North Jutland. This pumice is of intermediate composition and is almost identical in chemical composition and petrography with andesitic pumice and ash from the recent eruption of Hekla, as well as with similar finds of sub-fossil pumice on the coasts of western Norway, Novaya Zemlja, Spitsbergen and Greenland. It is therefore taken as highly probable that these pumices were derived from former eruptions of volcanoes in the Hekla region. A question thus arises as to the age of the beds in which the sub-fossil pumice has been found. In Jutland the pumice fragments are associated with rolled pieces of wood, lignite, hazel nuts, small pieces of amber, and one fragment of dopplerite—all light materials capable of floating in currents and liable to drifting and stranding on coasts. One of the beds is covered with peat of the Sub-boreal period. In western Norway the pumice bed is found on the uppermost *Tapes*-line, by which the time of the eruption that supplied the pumice can be fixed at about 2000 B.C. Hence it is probable that four thousand years ago the Hekla volcanoes were erupting material of a nature and composition similar to their present products. Prof. Noe-Nygaard finally envisages the possibility of establishing a synchronous level in the Quaternary beds of several Atlantic coasts by means of the Hekla pumice, in addition to the pollen analyses and archæological considerations which have hitherto been used for chronological purposes.

Ornithological Congress at Bamburgh

A BRITISH ornithological conference was held at Bamburgh, Northumberland, during June 26–July 1, under the joint auspices of the British Ornithologists' Union and the British Trust for Ornithology, local arrangements being in the hands of Dr. E. A. R. Ennion, director of the Monks' House Bird Observatory and Field Centre. Emphasis in the programme was on the field excursions. Members of the conference were able to visit the Farne Islands, which are National Trust bird sanctuaries with unique sea-bird colonies, and other interesting half-day visits were paid to Hulne Park, Alnwick, and to Chillingham and Ross Castle, where there is a memorial to Lord Grey of Fallodon. An all-day excursion was made to the Cheviot to see Northumbrian moorland habitats, and various short excursions were also made by small parties to other interesting localities. It is believed that at least 110 species were identified in the field during the conference, a striking indication of the wealth and variety of bird-life in north Northumberland. The indoor sessions, which took place in the Pavilion immediately below Bamburgh Castle, a setting specifically enhanced by the presence, on the rock face above, of several pairs of nesting fulmars, consisted of three discussions, six papers and two illustrated talks. The discussions, on fighting and threat in birds, on visible migration and on sea-bird populations, were led by Dr. N. Tinbergen, Colonel R. Meinertzhagen and James Fisher, respectively. The titles of the papers were as follows: high-water-mark ecology (E. A. R. Ennion), observations on the hawfinch (Guy Mountfort), the work of the Madingley Ornithological Field Station of the Department of Zoology, University of Cambridge (W. H. Thorpe), observations on the lapwing (K. G. Spencer), Northumberland birds (G. W. Temperley) and paper-tearing by birds (W. M. Logan Home). For his talk on "The Ornithological Year in Yorkshire", Mr. Ralph Chislett used some of his own fine collection of slides, and the other talk, on "The Pied Flycatcher at the Nest", by Bruce Campbell, was illustrated with slides from photographs by John Markham. In addition, members were entertained during one evening by Dr. and Mrs. Ennion at Monks' House, where the various trapping devices and other equipment of the Bird Observatory were demonstrated.

French Bibliographical Digest: Physics and Chemistry

NOS. 7 and 8 of "The French Bibliographical Digest", which have recently been issued (No. 7, pp. 87; No. 8, pp. 72. New York: French Embassy, 1951), deal with physics and chemistry respectively and complete the first series of bibliographical digests devoted to scientific works published in France during 1940–48. Several works published in the French language by Belgian and Swiss men of science are also included. A second series will list works published during 1949–51. The booklets contain, in addition to a useful list of the appropriate French scientific periodicals and publishers' addresses, the titles, with full bibliographical references, of the more important physics or chemistry books of university or more advanced standard. The inclusion of doctorate theses is most valuable. Many of the titles are accompanied by reviews, in English, reprinted by permission from British, American and French scientific journals. No prices are quoted because of the rapid fluctuations in exchange value. Prof. Y. Rocard, a member of the advisory board of the "Digest", contributes an introduction to No. 7, in which he describes briefly the effects of the German occupation on French physical research. He pays tribute to the many physicists, including H. Abraham, E. Bloch, G. Bruhat, F. Holweck, L. Cartan and J. Solomon, who died either in concentration camps or because of their participation in the resistance movement. Finally, he surveys briefly post-war activities and mentions the various French laboratories and the branches of research being pursued there. The chemistry booklet is similar in lay-out to the one on physics. The arrangement is alphabetical by authors under the following headings: chemistry, general; organic chemistry; inorganic chemistry; analytical chemistry; physical chemistry; industrial chemistry, technology and metallurgy; colloid chemistry; and biochemistry. Librarians, as well as research workers, will find the two booklets extremely useful for reference purposes.

Conception of Science in Education

The summer number of *The Use of English*, edited by Denys Thompson (Chatto and Windus), is notable for the amount of space which it devotes to the problems of teaching the humanities to the science specialist, particularly in the senior forms of grammar and public schools. F. W. Westaway, and more recently P. A. Gaskill and A. Towers, have already written excellent small books on English for science students. The editorial of the periodical under review goes further and gives a most useful outline of a scheme for enlarging the conception of science, its nature, its methods, its strength and its limitations in the field of knowledge. Such a scheme could well be developed for all sixth-formers in addition to those specializing in science. An excellent reading list on the values of science, science and civilization, the scope of science, science and religion, and science and politics is provided. The editor is wise in saying that "every sixth form teacher knows that it is not only the scientist who suffers from lack of balance and humility. In their refusal to see that true science is a major human activity, specialists in other subjects are quite as obtuse and obstinate as any scientist". This, indeed, is exemplified in another otherwise useful contribution by a writer in the same issue, who says: "Western civilisation is not only a weaving together of Greek, Roman and Hebrew strands; for good or ill we must admit the presence of modern western technology". Here again is the failure to realize that technology is a part of the application of science and not science itself. It now remains for some wise educationist to continue the work of redeeming the philistinism of so many students of the arts. Examples of this are only too common: for example, the master of the college who dreams of a neo-Hellenic Utopia but does not despise the use of anæsthetics and aeroplanes and adds to his income by broadcast talks.

National Museum of Canada, Ottawa: Annual Report for 1949–50

The year 1949–50 was an important one in the history of the National Museum of Canada, for it inaugurated a new era. The Museum began and grew up within the Geological Survey; but in 1920 the two were separated and placed under separate directors. They continued, however, to occupy the same building—the Victoria Memorial Museum—and to share some of the same services and even the same administration. By a reorganization which became effective in January 1950, the two passed into different government departments—the Geological Survey into the Department of Mines and Technical Surveys, and the National Museum into that of Resources and Development. This development is recorded in the annual report of the Museum for 1949–50 (Bulletin No. 23; pp. 261+60 pl.; 1951; 1 dollar). As is usual with museums in Canada and the United States, the Museum has been able to carry out an extensive series of expeditions and archæological excavations. The report gives details of field-work in zoology, undertaken in British Columbia, and botanical studies along the east coast of Hudson Bay; archæological sites were investigated on Cornwallis Island, North-West Territories, and in Manitoba and Saskatchewan. It is a matter worthy of note that these field exhibitions are undertaken as part of the normal work of the Museum, such is the faith of the trustees and managing bodies in their ultimate value to the Museum and the common weal.

Research at the University of Birmingham during 1950–51

The twenty-second annual report of the Joint Standing Committee for Research of the University of Birmingham covers the session 1950–51, in which the new Aitchison laboratories in the Department of Industrial Metallurgy were brought into use for teaching and research purposes. These laboratories consist of two main sections equipped with full-scale plant for foundry and for metal-working operations, and there is also a machine shop used principally for the construction of apparatus and for service and maintenance purposes. The laboratories, with modern manufacturing plant and equipment at their disposal have been constructed and equipped in the hope of supplying the metallurgical industries with men of good metallurgical training. The most valuable feature of the report is, as in previous years, the departmental lists of published work which is regarded as contributing to original knowledge. Each list i prefaced by a short note directing attention to specia features of the year's work. Three examples of such special features are as follows: in the Department of Mathematical Physics a new method has been evolved of treating bound states in field theory which has led to the development of new mathematical methods; work on the dielectric breakdown of pure liquids has now attracted a grant from the Department of Scientific and Industrial Research and the Department of Chemistry has been selected by the International Union of Chemistry as the British laboratory for the standardization of the molecular weights of high polymers.

University of London

The title of professor emeritus in the University has been conferred on the following: Prof. S. P Bedson (bacteriology), on his retirement from the Goldsmiths' Company's chair of bacteriology at the London Hospital Medical College which he has held since 1934; Sir David Brunt (meteorology), on his retirement from the chair of meteorology at the Imperial College of Science and Technology which he has held since 1934; Sir Alfred Egerton (chemica technology), on his retirement from the chair of chemical technology at the Imperial College of Science and Technology which he has held since 1936; Prof G. I. Finch (physical chemistry), on his retirement from the professorship at the Imperial College o science and technology which he has held since 1936 Prof. J. R. Marrack (chemical pathology), on his retirement from the chair of chemical pathology at the London Hospital Medical College which he has held since 1934; Prof. J. A. S. Ritson (mining), on his retirement from the chair of mining at the Imperial College of Science and Technology which he has held since 1935; Sir George Thomson (physics), on his retirement from the chair of physics at the Imperial College of Science and Technology which he has held since 1930.

The following other titles in the University have been conferred: reader in pharmacognosy on Dr J. W. Fairbairn, in respect of the post held by him at the School of Pharmacy; professor of pharmacology and therapeutics on Dr. C. A. Keele, in respect of the post held by him at the Middlesex Hospital Medical School; reader in biochemistry on Dr William Klyne, in respect of the post held by him at the Postgraduate Medical School of London; reader in bacteriology on Mr. B. W. Lacey, in respect of the post held by him at Westminster Medical School; professor of chemical pathology on Mr. N. H. Martin, in respect of the post held by him at St. George's Hospital Medical School; reader in morbid anatomy on Mr. A. D. Morgan, in respect of the post held by him at Westminster Medical School; reader in structural geology on Dr. Gilbert Wilson, in respect of the post held by him at the Imperial College of Science and Technology; degree of doctor of science on F. H. Burstall, P. C. C. Garnham, T. C. S. Morrison-Scott, Prof. Joseph Rotblat, D. B. Scott and Prof. P. E. Vernon.

Centrifuges and *p*H Meters

As a result of suggestions that existing models of centrifuges and *p*H meters have various and considerable disadvantages, the Institute of Biology is making a survey of the views of biologists on the desirable qualities of such instruments. It is hoped that the information obtained will enable the Institute to make constructive suggestions to manufacturers and will provide guidance for intending purchasers. Copies of questionnaires, one on centrifuges, the other on *p*H meters, may be obtained from the General Secretary, Institute of Biology, Tavistock House South, Tavistock Square, London, W.C.1.

Clayton Awards for 1952 of the Institution of Mechanical Engineers

UNDER the terms of the Clayton Bequest, the Institution of Mechanical Engineers has made the following awards for 1952 for special experience, postgraduate studies or research in mechanical engineering, the amounts totalling about £5,200 in value. *Clayton Fellowships:* B. J. Beale (Guildford), J. R. Botterill (Harrogate), F. J. Feltoe (Port Talbot), E. J. Forster (Bromley), P. M. Moreton (Whitchurch), C. E. H. Morris (Swansea), D. J. Myles (Arbroath), H. Naylor (Shipley), J. R. Willetts (Birmingham), R. G. Woolacott (London). *Clayton Grants:* C. K. Gulland (London), J. R. Plant (Burnley), J. L. Raynes (Bournemouth), T. F. Roylance (Allenton).

Institute of Metal Finishing: Endowment of New Awards

THE Council of the Institute of Metal Finishing has recently approved the establishment of the following awards. *Hothersall Memorial Medal and Lecture:* The Mond Nickel Company, Ltd., has endowed the annual award of a palladium medal (with which will be associated a sum of £50) for an initial period of seven years, in memory of the late Mr. A. W. Hothersall; the Council of the Institute will choose the recipient, who will then be asked to deliver a lecture. *Johnson Matthey Silver Medal:* This Medal, which has been endowed by Johnson Matthey and Co., Ltd., will be awarded annually, or at such times as may be decided by the Council, for the best paper presented to the Institute on the deposition of precious metals. *Westinghouse Brake and Signal Co., Ltd., Prize:* An award for the best publication appearing in the *Journal* of the Institute, which, in the opinion of the Publications Committee, shows the most valuable advance in the science or practice of electrochemistry in general and electrodeposition in particular, has been endowed by the Westinghouse Brake and Signal Co., Ltd., for a preliminary period of seven years; it will amount to £25 annually and will consist mainly of a selection of books. In the case of the last two awards, both members and non-members of the Institute are equally eligible, and papers should be submitted direct to the Institute at 32 Great Ormond Street, London, W.C.1.

International Astronomical Union: General Assembly at Rome

THE eighth General Assembly of the International Astronomical Union will be held in Rome during September 4–13. The inaugural ceremony will take place in the Campidoglio, in the Hall of the Orazi and Curiazi, and other sessions will be in the University of Rome and near by in the building of the Italian National Research Council. Besides the various Commission meetings, the programme will include three symposia on stellar evolution, astronomical instruments and the astrometry of faint stars, respectively. In addition, excursions will be made to the Castelli Romani, with a stop at Castel Gandolfo for visiting the Vatican Observatory, and to the archæological excavations at Ostia Antica. Non-members of the International Astronomical Union may participate in the Congress on payment of a fee of 5,000 lire. Further information can be obtained from the assistant secretary-general of the Union, Prof. P. Th. Oosterhoff, Leyden Observatory, The Netherlands.

Beta- and Gamma-Ray Radioactivity: Conference in Amsterdam

A CONFERENCE on beta- and gamma-ray radioactivity, which has been organized by the Netherlands Physical Society with the support of the International Union of Pure and Applied Physics and of Unesco, will be held in Amsterdam during September 1–6 under the presidency of Prof. G. J. Sizoo. The conference will be open to all nationalities and will consist of invited papers of about forty-five minutes in duration, and short communications, to be given by guests or visitors, of about fifteen minutes in duration. The principal sessions and headquarters of the conference will be at the Koninklijk Instituut voor de Tropen, Mauritskade 63, Amsterdam-O; the sectional meeting on the Monday afternoon will be held in the Vrije Universiteit, de Lairessestraat 174, and those on Wednesday and Friday afternoons in the physical laboratories, Plantage Muidergracht 4–6. All the lectures will be published in a special issue of ***Physica***. Further information regarding the conference can be obtained from Prof. J. de Boer, Bunsenstraat 98, Amsterdam-O.

Announcements

WE regret to announce the death on August 5 of Sir Jack Drummond, F.R.S., director of research to Boots Pure Drug Co., Ltd., and of Lady Drummond, both well known for their work on human nutrition.

PROF. PAUL KARRER, professor of organic and practical chemistry in the University of Zurich, has been elected a foreign associate of the Paris Academy of Sciences in succession to the late Sir Charles Sherrington; Prof. Maurice Fréchet, honorary professor in the Faculty of Sciences, University of Paris, has been elected *correspondant* for the Geometry Section of the Academy in succession to the late Prof. G. Castelnuovo.

DR. S. KRISHNA has been appointed deputy director of the Council of Scientific and Industrial Research, New Delhi, on the expiry of his term of office as Scientific Liaison Officer for India in Great Britain.

PROSPECTING BY GEOPHYSICAL METHODS

THE European Association of Exploration Geophysicists held its second meeting at Manson House, London, during May 22 and 23. About ninety members and visitors attended, half of whom came from abroad. The Society of Exploration Geophysicists of the U.S.A., with which the Association has close ties, was represented by its official delegate, Dr. Alexander Wolf, of Houston, Texas, and the chair was taken, in turn, by the president, Mr. van Weelden (Netherlands), and Mr. G. Westby, president of the Seismograph Service Corporation of the U.S.A. Nine technical papers from France, Germany and Great Britain were presented. Four of these related to seismic prospecting, three mainly to gravity and two to the telluric current method.

In a paper presented by Mr. H. Linsser (Germany) the author attempted to explain, in a simple manner illustrated by diagrams, the mechanisms of a seismic explosion, and to decide which phases of the explosion contribute to the seismic energy propagated. His investigations were supported by experiments, and he has come to the rather surprising conclusion that no perceptible ground motion is set up by a rarefaction wave following the initial compressional impulse. The latter creates a zone of deformation within which the rock medium is stressed beyond the elastic limit and compressed: and apparently this zone assumes a permanent set which withstands the rarefaction rebound.

The significance of diffraction in the detection and mapping of faults was the subject of a paper by Mr. T. Krey (Germany). By theoretical treatment and field observations, Mr. Krey has demonstrated that the overlapping on a seismic record of reflexions from a faulted bed is not necessarily due to thrust faulting or, in the case of a normal fault, a difference in dip of the bed on either side of the fault: it can be due to the effect of diffraction at the edges of the faulted bed. The attenuation of the energy of the diffracted waves with distance from the fault is gradual, and makes precise location of the fault a difficult problem. When employing the customary interpretation technique, the error involved could be of the order of hundreds of feet, and depends on the depth of the reflecting bed and the signal-to-noise ratio of the seismic recording. Errors may also result in the determination of dip.

In stressing the importance of this paper, Dr. A. Wolf suggested that the practical implications of diffracted waves in seismic prospecting were not fully appreciated. He had been able to register them by using geophones connected in opposition and placed 200–300 ft. apart. With such an arrangement the normal reflexions would not be recorded; but waves diffracted at a fault would arrive at the two geophones out of phase and would be registered. In this way he had successfully located faults in the United States.

Mr. J. Goguel (France) described a special slide-rule which he has developed for the rapid determination of the depths of a series of refracting beds, with small dip, from the observed time-curve. The design of the slide-rule is based on the 'intercept time' method of depth calculation and, when adjusted for the velocity values determined from the time curve, it furnishes directly the cosine factors which are required in the depth formulæ.

Laboratory investigations on the variation of the elastic constants of rocks with frequency were described by Prof. J. M. Bruckshaw and Mr. P. C. Mahanta (Great Britain). It is an established fact that there is an appreciable difference (up to 20 per cent) between the statically determined elastic modulus and the effective value at high frequencies, and the experiments described were designed chiefly to secure further information on this change. American investigators have demonstrated that no appreciable change occurs over the frequency-range 140–4,500 c./s., and the authors' investigations were therefore confined to a lower region, between 40 and 120 c./s.

Measurements made on six different rock specimens exhibited a gradual increase of Young's modulus with frequency, but the total increase over the frequency-range employed was only 2·1–2·6 per cent. The trend of the curves suggested that considerably greater changes could be anticipated below 40 c./s. The authors made use of the results to demonstrate the magnitude of the internal dissipation of energy over the frequency-range considered and were able, also, to show that the influence of dispersion in seismic prospecting is unlikely to cause appreciable error in the interpretation of field seismograms.

Much attention has been paid in recent years to the problem of securing the maximum information from gravimeter observations by devising improved methods of removing the effect of the 'regional anomaly'. Papers relating to this problem were presented by Dr. O. Rosenbach (Germany) and Dr. V. Baranov (France).

The former described a development of the 'second derivative' method of interpretation originally published by T. A. Elkins[1]. Dr. Rosenbach explained that Elkins's formula, while applying quite satisfactorily to deep-seated structures which give rise to low fluctuations of the second derivative at surface, cannot handle adequately the more extreme variations of the second derivative which result from density anomalies at shallower depths. The new approach which he described is to expand the gravity values at suitably spaced points on concentric circles as series in G_P (the gravity at the centre) and its derivatives. By combining sets of these series he has derived practical formulæ which furnish a very close approximation to the theoretical curve for the second derivative.

Dr. V. Baranov presented an interesting analytical method of determining the regional anomaly. The problem in practice is to divide the Bouguer anomaly, B, into two component parts, $B = R + A$, R being the regional anomaly and A the sum of the residual anomalies. The isogals which define the regional gravity anomaly should exhibit only slight curvature and should be fairly regularly spaced. Dr. Baranov therefore assumes that the anomaly can be expressed as an analytical function which may be expanded in a power series, and he neglects terms beyond those of the second or third degree. In order to determine the coefficients of this function, he utilizes the conlition that the residual anomalies, A, have only a ery limited influence, which implies that the integral

$$\psi = \iint (B - R)^2 \, dx \, dy,$$

ver the area within which the regional anomaly is equired, is a minimum. A complete description of he method was presented, and illustrated by practical xamples.

The discussion which followed these two papers on gravity was very lively, and some speakers, led by Prof. Vening Meinez, expressed their doubts of the real practical value of the various methods which attempt to eliminate the 'regional effect' from the Bouguer picture. Dr. Rosenbach, in his reply, emphasized the importance of an appreciation of the scale of the problem in gravity prospecting. It must be realized that a very close network of stations is adopted, and that the modern gravimeter can be read with an accuracy of at least 0·1 milligal.

Prof. K. Jung (Germany) described two elegant geometrical constructions for determining the approximate positions of buried bodies of simple form from their gravity or magnetic anomalies. He explained that these constructions were developed for use by geologists and others with a restricted mathematical background who require to assess roughly the results of a geophysical survey. He described also a simple mathematical development of Nettleton's method of determining near-surface densities from a series of gravity observations along a profile over a topographical feature.

The telluric current method of prospecting has been developed and used with considerable success by French geophysicists. A paper by Mr. M. Mainguy and Mr. A. Grepin (France), describing some practical examples of interpretation of telluric maps obtained in Languedoc (south-east France), was written from the point of view of a geologist, and was therefore of particular interest. The results of telluric surveys in the Beziers and Alés–Maruéjols basins and the Lunel area were described, and compared with gravity and seismic investigations in the same areas.

The outstanding feature of this particular geophysical work is that, in general, the telluric method has apparently furnished more detailed and accurate information than any other method. In the case of the Alés–Maruéjols survey, the results of the telluric observations contradicted to a considerable extent the prevailing geological ideas and the findings of other geophysical methods; but subsequent drilling evidence confirmed the accuracy of the telluric interpretation and resulted in the discovery of oil. In the Beziers basin the telluric results agreed quite well with the gravity findings, but, in common with the seismic work, the method was unable to secure detail from the depths required. The survey in the Lunel area was very difficult to interpret, but despite this the telluric method appears to be the most promising one to employ.

Mr. G. Kunetz (France) dealt with the problem of eliminating the effect on telluric observations of stray earth currents originating from installations such as electric railways, tramway systems, etc. For surveys where the source of disturbance is, say, a large industrial town at a considerable distance, it is possible to represent the disturbing field approximately by a function the parameters of which can be determined experimentally. A 'regional anomaly' map can thus be produced. Where the disturbing source, or sources, are in the immediate proximity, and the parasitic currents are liable to violent fluctuations, much more laborious methods are required, involving numerous field measurements. It speaks highly of the work of our French colleagues that it has been found possible to produce telluric maps of practical value in such difficult circumstances.

D. T. GERMAIN-JONES

CONFERENCE ON FERTILITY

THE scientific proceedings of the third annual Conference on Fertility, held by the Society for the Study of Fertility in London during June 27 and 28, were opened by Dr. Carl G. Hartman (United States), who presented formidable evidence for the theory of germ-plasm defect as a major cause of fœtal wastage. His early studies on the aplacental opossum, in which he found some 10 per cent of all the developing eggs to be grossly faulty, led him to favour the view put forward by Streeter—that early death of the embryo was due mainly to defective germ plasm—rather than the older idea of Mall that implantational defects were chiefly responsible. Later studies on mouse eggs, using intra-vital staining techniques, supported the same view by demonstrating, in many instances, dead and living blastomeres within the same zygote. He referred also to the recent studies by Hertig and Rock of early human ova; in none of the cases wherein these were abnormal did the authors find any evidence of endometrial deficiencies, although Dr. Hartman admitted that Hughes has claimed that a lack of a glycogen could be demonstrated in the endometrium in some cases of early abortion.

Prof. S. A. Asdell (United States) gave a provocative contribution on the effect of intelligence upon fertility, basing his conclusions on a study of the pedigrees of royal houses. Although the assessment of 'intelligence' was made as objective as possible, he admitted the possibility of many sources of error. Nevertheless, with the exception of genius, which appears to make its own laws, definite correlations appeared to exist, many of which were contrary to popular beliefs. Thus, although the incidence of inbreeding decreased with rising intelligence, the proportion of childless marriages was highest with least intelligence and smallest with average intelligence, and the number of children in the family was highest with average intelligence. It seemed that Nature favoured the average in intelligence, as in most other biological attributes. Another finding was that, contrary to Galton's view, the families of only children of high intelligence (judges who had been elevated to the peerage in Stuart and Georgian times) tended to be large, averaging five to six offspring. Naturally, this paper evoked lively discussion.

Prof. S. Zuckerman (Birmingham) reviewed the cellular components of the ovary, particularly from the point of view of their plasticity. He referred to his own recent work, which leads him to conclude that, in the rat at least, no formation of new oocytes from the germinal epithelium occurs in the adult. He considers the function of the germinal epithelium to be mainly protective; it is highly phagocytic and resilient, continually changing in size and shape as follicles mature and corpora lutea develop and regress. He stressed its sensitivity to trauma, to which it responds vigorously by the formation of ingrowths and outgrowths. The other highly plastic element of the ovary is the theca interna cell, which transforms from a fibroblastic cell into an epithelioid secreting cell, luteinizes to become—very likely—the only functional endocrine element of the corpus luteum, and finally can become transformed back into a fibroblastic structure.

Dr. Henri Bayle (Paris) discussed spermatophagia in the human epididymis in cases of excurrent duct obstruction and showed slides of spermatorrhage—rupture of the epididymal tubules through excessive internal pressure, with outflow of spermatozoa into the peritubular spaces, leading to oblrteration of the epididymal canal. He then demonstrated his film showing the operative technique of vaso-epididymostomy; the beauty and lucidity of this film are beyond description. Dr. Bayle does not perform testicular biopsy first, but prefers to incise the head of the epididymis after having mobilized the testicle; if moving spermatozoa are seen in the epididymal fluid, he proceeds with the operation, provided patency of the vas deferens can be demonstrated. He uses seven sutures of fine tantalum wire to anastomose the vas to the epididymis. Delicacy of touch and the avoidance of trauma are the prime requisites of success in this difficult operation. Out of 143 cases explored surgically, anastomosis was found impossible in thirty cases, and in a further six congenital absence of the vas was discovered. Vaso-epididymostomy was performed bilaterally in sixty cases, and unilaterally in forty-five; in a further four cases anastomosis of the vas deferens direct to the testicles was attempted. Of sixty-five surgically satisfactory cases, the azoospermia was cured in forty-five (66 per cent), twenty of these men producing in all thirty-two children. This rate of success, of course, is far better than any other surgeon has achieved.

The morning of June 28 was devoted to a symposium on spermatozoan morphology; this was opened by Prof. L. Harvey (Exeter), who gave a review of spermatogenesis and spermateliosis. The National Institute for Medical Research team of workers (C. F. Challice, P. E. Lake, E. J. C. Polge and J. Smiles) reported ultra-violet microscopy studies on living fowl germ cells and electron-microscope studies of mouse and rabbit spermatozoa. They showed how the Golgi zone of the fowl spermatid developed into the acrosome. The tail filament was found to be motile from the earliest stage, the tail granule being the source of motility. Chromosome material aggregates, becoming a homogeneous mass within the nuclear membrane. It then elongates, later to shrink, leaving behind a free portion of the nuclear membrane, thus forming the manchette which later forms a rigid tube around the first part of the tail. Considerable advances in our knowledge of the morphology of rabbit and mouse spermatozoa have been afforded by the technique developed by these workers of cutting sections 0·2 μ thick followed by electron microscopy. There is strong evidence for a double spiral structure of the mid-piece and tail around the axial filament, all within a fine outer membrane. The axial filament contains nine fibrils arranged circularly around a central one, and there appears to be a flange running lengthwise down the tail.

Mr. Geoffrey Grigg (Cambridge) also contributed electron-microscope studies on fowl spermatozoa, his findings being mainly in agreement with those of the previous speakers. The apical cap dissolves in distilled water, leaving the apical spine partly embedded in the head. He has regularly found eleven fibrils in the axial filament—two central and nine outer. There seems to be an inner core to each fibril which is more elastic and more resistant to tryptic digestion than the surrounding material. Dr. Bayle showed electron-microscope photographs of human spermatozoa. Dr. John McLeod (United States) discussed spermatozoan morphology in relation to human fertility and, as a result of his large-scale studies, he has come to the conclusion that little correlation between sperm morphology and fertility can be discovered in the human. Poor morphology is commonly associated with poor motility—which has a very definite bearing on fertility—but otherwise, provided the sperm density exceeds 20 millions per ml. and the percentage of active cells is not much below 40, fertility seems to depend mainly upon the quality of sperm motion.

Dr. John Wilkinson (Exeter) described the effects of aspermy virus upon nuclear behaviour in solanaceous plants. In the pollen and embryo sac mother cells, the pachytene threads become disorganized in the prophase of meiosis and the nucleoli are multiplied. Some of the chromosomes fail to pair, leaving behind univalents at metaphase and anaphase. This probably accounts for the 25 per cent diminution in seed production shown by affected plants. It was suggested that a competition may exist between the virus and the chromonematal material of the chromosomes for ribose-nucleic acid. Mrs. C. Harvey (Exeter) said she had made similar observations on testicular biopsy material from subfertile men, having also noted collapse of the chromonemata at prophase and loose and lagging chromosomes at metaphase and anaphase. This seemed to suggest a possible viral etiology for some cases of human male infertility.

In the last two papers, Dr. F. X. Gassner (United States) showed that the rate of fructolysis in seminal fluid is better correlated with the breeding efficiency of bulls than the conventional criteria of seminal analysis, and Dr. E. W. Macmillan (Liverpool) described the vascular pattern of the epididymis in the rat and the sequence of changes in the epididymis and testis following interruption of the superior epididymal and accessory capital arteries; the vasa efferentia became packed with spermatozoa, which led to their gross enlargement and to severe degenerative changes within the testis, while the caput epididymis underwent necrobiosis followed by obliterative fibrosis.

EMULSIONS AND FILMS

SYMPOSIUM AT SHEFFIELD

THE British Society of Rheology organized a symposium on "Emulsions and Films" which was held in the University of Sheffield during March 28–29. All the papers were followed by discussion, and on the second day the meeting visited the chemistry laboratories of the University and inspected the apparatus used by the speakers at the meeting.

In the first paper, Dr. A. S. C. Lawrence pointed out that emulsions are always placed in a separate category of colloids as liquid-in-liquid systems—a classification to which objection can be made on two grounds: the fact that the liquid state of the disperse phase makes possible dispersion by shaking is of no fundamental importance (it is not even true for dispersions of true colloidal size, that is, oil hydrosols which are typical hydrophobic systems) ; and it has distracted attention from the really basic criteria—namely, that, although hydrophobic, very high concentrations (74 per cent) of the disperse phase are easily attained, and the particle size is much larger than in all other hydrophobic colloidal solutions. Emulsions are not, strictly, colloids at all ; they are opaque, and sedimentation, as creaming, is one of their most distinctive properties. They belong, in fact, to the neglected class of protected colloids.

It has become accepted that the stability of emulsions is due to the lowering of the free surface energy of the system by adsorption of surface-active emulsifying agent and that interfacial tension is a coagulating tendency'. This error of identifying the potential reduction of free energy with the driving force causing the reduction is one against which students learning thermodynamics are warned year after year. In any case, a lowering of the free surface energy can reduce only potential instability and cannot give an absolute stability : even if this thermodynamic quantity were the driving force in coagulation, reduction to zero would be required to give absolute stability. This, however, is the condition for miscibility of the two phases, and it is also a characteristic of emulsions that there is some residual interfacial surface tension which is responsible for the spherical shape of the droplets of the disperse phase. The emulsifying agent should be regarded as an energy barrier which is needed, as in all hydrophobic systems, to prevent aggregation or coalescence of particles subsequent to collisions due to their Brownian motion. The action of the energy barrier is to prevent coalescence following collision ; it has no effect upon collision frequency. The mean Brownian velocity depends upon T and inversely upon η—that is, the viscosity of the continuous phase and not that of the whole emulsion, which is always larger, usually by a large factor. Collision frequency will be highly dependent upon concentration obviously as a function of the cube root of it, since it is dependent upon the mean distance of separation of the droplets, all other factors being the same. Creaming will always increase collision frequency because it reduces the mean separation distance. For fine dispersions, Brownian motion is the rate-determining factor in the collision process. but, as particle size increases, sedimentation becomes increasingly the rate-determining factor. Every chemist has had the opportunity of seeing this transition every time he has done an ether extraction. This kinetic picture must be extended because there will be a Maxwell distribution of Brownian velocities, and the number with sufficient energy to overcome the energy barrier to coalescence, E, will be given by the usual $n/n_0 = \exp(-E/RT)$. 'Stability' means that n/n_0 is vanishingly small.

Surface tension has no place in this scheme ; it determines the work to be done in dividing the disperse phase ; it has nothing to do with the stability of emulsions. Adsorption of the emulsifying agent to the interface requires that it must lower the interfacial tension, but this lowering need not be large. It could be said that surface tension is involved in the coalescence stage in breaking : since, however, the first step in coalescence must involve an increase of the surface area of two spherical drops, it would appear that high interfacial tension will resist this step while a low value favours it and, therefore, instability—again, this is the opposite to the accepted view that low interfacial tension favours stability.

The energy barrier provided by the emulsifying layer may be electrical, mechanical or due to surface tension. The last-named class consists of powders acting by a differential wetting-angle with the two phases. Amphipathic substances which are also ionized may be good emulsifiers but some are not. It therefore seems that some other property is concerned, and Dr. Lawrence suggested that this is viscosity ; either a high two-dimensional η or a plasticity. It is likely, but not proved, that objection may be made against rigidity in the sense that, when such a layer is fractured, it cannot spread again to close a gap. Dr. Lawrence's emulsions of sea water in fuel oil are a case in which very high surface viscosity, without a charge and with very slight surface activity, is responsible for stability.

The work carried out in Sheffield which Dr. Lawrence reported to the meeting is based upon the following idea. The viscosity of the continuous medium may be increased and therefore reduce ξ and, therefore, collision frequency, but this is only a reduction : it cannot give absolute stability in a liquid system. The high and anomalous viscosity of an emulsion of 50 per cent or more oil in soap solution is an indication of the surface viscosity of the emulsifying layer : laminar flow requires droplets to slip between their neighbours and, to do so, they must be distorted into ellipsoids ; if, after passing, they relax to spheres before the next passage, the work used in deforming them will be dissipated as a micro-turbulence of the liquid medium associated with the flow of the droplet, and non-Newtonian flow will result. One immediate result is that the extent of the anomalous viscosity will be proportional to the surface area of the drops ; that is, inversely proportional to their diameter. Direct measurements have been made of the surface viscosity and plasticity of solutions of soaps with various polar groups.

Other researches in progress at Sheffield are an investigation of the kinetics of coagulation using micro-photographic recording with phase-contrast objectives—no method exists for assessing the stability of emulsions other than counts of particle size. Some less laborious method is urgently needed and is under consideration. ζ potentials are also being studied, and a drop-profile apparatus is being used for measuring interfacial tensions, especially when small. The work is being extended to the action of complexes of soap plus a molecule containing a polar group such as carboxyl, hydroxyl or amine.

The present views upon which the work is proceeding are fourfold : that best emulsifying efficiency requires the closest packing of the soap molecules at the interface ; that soaps alone are not the best emulsifiers (carboxylates are an apparent exception because the acid soap is the useful agent) ; that closest packing and maximum efficiency are provided by complexes of soaps (of all sorts) and molecules containing a hydrocarbon chain of not less than six normal carbon atoms and a polar group such as hydroxyl, carboxyl or amine ; and that these complexes, at sufficient concentration in bulk, are all liquid crystalline of the smectic type.

Mr. E. Rothwell (University of Sheffield and Imperial Chemical Industries, Ltd., Ardeer) reviewed the work of Hatschek and Sibree and the later empirical relations between η and concentration proposed by Richardson, Broughton and Squires and by Goodeve. He then mentioned the work of Rossi, Lyttleton and Traxler and of Richardson upon the effect of particle size upon η. He described his own experimental work with particular reference to the effects of the packing-density in the emulsifying layer, to the effect of particle size and to the composition of the soap adsorbed at the interface. η was inversely proportional to particle size diameter for a given physical state of the emulsifier layer. For a given particle size viscosity decreases with increase of area per molecule adsorbed—that is, viscosity increases with increase of packing density, and therefore with fall of interfacial tension. This proves that the work done in flow in deforming droplets is not work done against γ, since that would require η to vary with γ in the opposite sense to that found, and the work must therefore be done against a surface viscosity, plasticity or elasticity. In agreement with Hatschek, it was found that, at very low rates of shear, η is independent of rate of shear corresponding with a complete relaxation of droplets between successive distortion; η then falls with increase of rate of shear but becomes constant again at high values corresponding with permanent distortion during flow.

The next speaker, Mr. B. C. Blakey (University of Sheffield), described measurements of the surface viscosity of soap solutions by the oscillating bob method. Sodium carboxylates, sodium alkyl sulphates and kationic soaps all have a high surface viscosity which is non-Newtonian except in the *n*-alkyl sulphates: the kationic soaps developed surface viscosity only on standing. The minimum concentration for appearance of surface viscosity is well below the critical concentration: in the carboxylate series, η rises with increase of chain length at 20° C. Sodium soaps have a higher value than that for potassium compounds. The effect is very large; for solutions of sodium cetyl sulphate the viscous drag on the bob due to the surface viscosity is equivalent to an immersion in water of the bob of 2–5 in.

The greatest care needs to be taken to exclude impurities even in very minute concentrations, and fractionation by frothing is especially valuable as a check. The addition of fatty acid to a carboxylate soap causes surface viscosity to appear at lower concentration than for the soap alone; but alkali has the opposite effect, which suggests that the surface species is acid soap. Alkyl trimethylammonium soaps showed a pronounced maximum at the critical concentration, the most obvious explanation of which was impurity which was solubilized at the higher concentrations. This has since been confirmed. A solution sufficiently pure to show no minimum in the surface tension concentration curve did give a maximum in the surface viscosity curve, and surface viscosity is therefore a more sensitive method for detection of small amounts of impurity than is surface tension. The sodium alkyl sulphates show Newtonian surface and interfacial viscosities when pure, but anomalous when not rigorously purified.

Work on solubilization of substances such as alcohols and fatty acids upon soaps was described by Mr. A. J. Hyde (University of Sheffield). This differs from solubilization of hydrocarbons in two fundamental respects: the inert substance in excess passes to emulsion, the polar addition, as soon as excess is added, separates with the soap as a liquid layer, the other being water, and the soap additive complex becomes oleophilic; at sufficient concentration and with a longer hydrocarbon chain in the additive, liquid crystals of the smectic layer type are always formed. The texture of the smectic phase varies with the composition giving either anisotropic spherulites; Dupin's cyclides or myelinic figures. The last are usually of the normal curved form, but occasionally have sharp angles as if simulating crystals. The general scheme seems to be:

spherical micelle in soap solution + additive →
smectic layer complex

With less hydrophobic additive, for example, benzyl alcohol, considerable further lowering of surface tension occurs, paralleled by charges of electrica conductivity. This lowering of surface tension must mean closer packing in the adsorbed film. With these more hydrophilic complexes, emulsification does not take place.

In a theoretical paper on the rheological behaviour of an emulsion, Dr. J. G. Oldroyd (Research Laboratory, Courtaulds, Ltd., Maidenhead) described how a finite interfacial tension between the two phases must give rise to elastic as well as viscous properties, since it provides a force tending to restore each deformed droplet of the disperse phase to its original spherical form. On the assumption that the droplet size is sufficiently small and uniform, an equation of state for a dilute emulsion subjected to small rates of strain was derived in the form of a linear relation between stress, rate of change of stress, rate of strain, and rate of change of rate of strain. The three constants in the equation were expressed in terms of the viscosities of the two phases, the interfacial tension and the volume concentration. The predicted effect of introducing a stabilizer would be principally to increase the relaxation time and retardation time of the system (by decreasing the interfacial tension) without changing the viscosity. But if hydrodynamic slipping were possible at the droplet boundaries due to the presence of a film of stabilizer, all three constants would be affected; preliminary calculations showed that it might be very difficult to detect slipping of this kind experimentally.

A. S. C. LAWRENCE

SECOND SEMINAR FOR EUROPEAN SANITARY ENGINEERS

THE second seminar for European sanitary engineers, sponsored by the Italian Government, the Rockefeller Foundation and the United Nations World Health Organization, was held in Rome during November 1951; representatives from sixteen European countries attended. The report of this meeting, published by the World Health Organization*, contains a great deal of information, which has not hitherto been easily available, on sanitary conditions on the Continent.

There was general agreement that there should be closer collaboration between sanitary engineers in different European countries. Many rivers, for example, flow through more than one country before reaching the sea, and it is clearly desirable that the discharge to them of polluting substances should be controlled in the common interest. The problems which arise in this kind of international planning are, of course, partly political, but are more likely to be solved if there is general agreement on the technical issues involved. At present the importance of the profession of sanitary engineering differs a good deal from country to country, and there is no general agreement on what the basic training of a sanitary engineer should be. Generally, however, this training falls somewhere between the two extremes represented by United States and British practice. In the former the student is trained in a university school of sanitary engineering, whereas in Great Britain the sanitary engineer is a man who is first trained in civil engineering and then specializes in the field of sanitation or public health. It may be mentioned, however, that in addition to a sanitary engineer thus defined, there are in Great Britain many men working in the field of sanitation whose basic training was in chemistry or biology and who are usually members of the Royal Sanitary Institute or the Institute of Sewage Purification, or who are professional associates of the Institution of Water Engineers. In this matter of training, there is probably no one best way, and the method found most efficient for any particular country will depend on the complexity and importance of the problems to be solved.

---

* World Health Organization. Second Seminar for European Sanitary Engineers, Rome, 11–17 November 1951. Pp. v+280. (Geneva: World Health Organization, 1952.)

There was general agreement at the seminar that the ultimate formation of an international association of sanitary engineers is desirable. Here it may be recalled that a somewhat similar body—the International Water Supply Association, formed in 1947—is flourishing strongly and is holding its second congress in Paris this year. Some of the problems which would be encountered in introducing any standardization in sanitary matters in Europe were apparent in the discussion of a paper by Prof. U. A. Corti, of Switzerland, on the possible development of international standards for drinking water. Until recently there was general agreement on the more obvious standards required in a potable water—the absence, for example, of toxic metals and of pathogenic bacteria. It is clear, however, that if an attempt were made at present to lay down precise standards for all the minor constituents found in natural waters, or added during the course of treatment, a wide difference of opinion would be revealed. This is obvious, indeed, from the discussions which have followed recent proposals to add fluoride to water to reduce the incidence of dental decay. In any proposal to develop international standards the first step would seem to be to introduce standard methods of chemical analysis and bacteriological examination, and this point was made by several speakers during the discussion.

An important part of the Seminar was given up to discussions on the treatment and disposal of sewage, particularly from single houses and small communities. Installations of this kind, consisting usually of a septic tank and percolating filter, are in common use in some parts of the Continent and, to a small extent, in rural districts in Great Britain. Although they are one of the earliest types of treatment plant, surprisingly little is known about the principles on which their operation depends. This applies also to the disposal of the final effluent—which may contain pathogenic organisms—by subsurface irrigation, and much more work on this subject is required. It may be mentioned, for example, that in some parts of Great Britain lack of knowledge of the movement of liquids underground, and of the removal of bacteria from them in passing through various formations, limits the disposal of household refuse by controlled tipping in abandoned gravel pits—a method which has the advantage of being the cheapest form of disposal and of reclaiming otherwise derelict land. The seminar concluded with a very well-documented paper by Prof. M. Petrick, of Yugoslavia, on the utilization of night-soil and sewage sludge in agriculture, a subject on which there is now a considerable amount of quantitative information. There was general agreement that the series of seminars for European sanitary engineers should be continued, and it has since been announced that the third will be held in Great Britain in October this year.

BIOLOGICAL ASSESSMENT OF CHEMOTHERAPEUTICS

THE Biological Methods Group of the Society of Public Analysts and Other Analytical Chemists held its summer meeting in Nottingham during June 12–13, at the invitation of the directors of Boots Pure Drug Co., Ltd.

On June 12, the members of the Group visited the Pharmacology and Bacteriology Divisions of the Research Department, and the Bio-Assay Division of the Standards Department. In the Pharmacology Division demonstrations were given of the methods used for examining new substances for chemotherapeutic activity against the organisms of some tropical diseases, including amœbiasis, leishmaniasis, schistosomiasis and trypanosomiasis. Particularly interesting was the exhibit showing all stages of the life-cycle of *Schistosoma mansoni*, including ova, miracidia, cercariæ and adult worms. A demonstration was given of the value of the phase-contrast microscope for the examination of living, unstained Protozoa.

A cartesian diver apparatus was shown in use to measure the rates of oxygen uptake of small numbers of *Trypanosoma congolense* under various conditions. The apparatus was based on that first described by Linderstrøm-Lang: it has been adapted for use at 37° C., and to allow addition of substrates and inhibitors to the respiring organisms.

The examination of compounds for anti-tumour activity was demonstrated. Transplanted tumours such as the Walker carcinoma in rats and the mouse sarcoma 37 were shown, and the effect of the administration of such substances as nitrogen mustard and triethylene melamine on their development.

Methods of assessment of pharmacodynamic activity in new compounds which were shown included the estimation of local anæsthetic activity by a modification of the Bulbring–Wajda method, and the estimation of antihistamine and bronchodilator activities by the inhibition of bronchoconstriction produced in guinea pigs by the intravenous injection of histamine and other bronchoconstrictor agents. A demonstration was given of a possible method of assessing cortisone-like activity by the inhibition of granuloma-formation around implanted cotton-wool pellets and other foreign bodies in the rat.

Methods for examining acute and chronic systemic toxicity were demonstrated: a simple device was shown for dispensing drug-containing diet to mice in such a way that the daily consumption can be accurately measured. Several methods of assessing local toxicity and tissue damage were shown, including intradermal injection in guinea pigs, prolonged surface application to the shaved abdomen of mice under a fluid-tight cap, and the use of a small glass vacuum-cup to extract histamine-containing tissue fluid through the skin of a rat immediately over the site of a subcutaneous injection of an irritant substance.

In the Bacteriology Division, demonstrations were given of the various techniques used in the screening of new substances for possible activity against bacteria, viruses, and pathogenic fungi. In the Tuberculosis Section, the animal room was shown in which infected animals are maintained behind glass in a continuous current of air drawn into the room and expelled through filters. Laboratory demonstrations showed *in vitro* tests by the floating pellicle technique, and *in vivo* tests using guinea pigs and intracerebrally infected mice, and the method of assessment of drug activity on the basis of gross pathology. Groups of lungs taken from tuberculous mice, treated with known drugs such as *p*-aminosalicylic acid, thiacetazone, streptomycin, isonicotinic acid hydrazide, etc., were shown.

In the Virus Section, the use of bacteriophage as a screening virus was demonstrated. Methods with embryonated eggs for screening against influenza *A* and other viruses were shown, and with chicks against the Rous sarcoma virus. In the General Chemotherapy Section, a demonstration was given of an *in vivo* test in mice for the assessment of delay activity in penicillin preparations.

The Antibiotic Section showed the types of small-scale fermenters used for the experimental study of antibiotic production by new mutants of *Penicillium chrysogenum* or by newly isolated organisms. These included revolving tubes, shaker flasks, and larger fermenters. Methods of isolation and study of new organisms were displayed, as also were the biochemical studies carried out on the cultures during fermentations.

In the Bio-Assay Division, demonstrations included the assay of routine batches of insulin using the mouse convulsion method, and the determination of the delay activity exhibited by protamine zinc insulin in rabbits. The use of thermocouples for the determination of the rectal temperature of rabbits in pyrogen tests was shown. Other exhibits included the sulphated ox blood method of heparin assay, the rat 'line test' technique for the estimation of vitamin D and the standardization of posterior pituitary extract using the isolated uterus of the guinea pig.

On June 13 the Group visited the Veterinary Science Division at Thurgarton Priory. Demonstrations were given of the symptomatology and pathology of blackhead infection in turkeys, and methods of producing infection artificially were discussed: the use of artificially infected poults for drug assessment was described. Methods employed for the evaluation of new drugs against the common helminth parasites of domestic animals included a simple *in vivo* screening method using the free-living nematode *Turbatrix aceti*, cultured in serial dilutions of the drug.

A demonstration of work on Johnes disease in cattle included pathological specimens showing massive infection of the tissues. A brief account of the naturally occurring disease was given, and attempts at treatment with streptomycin and thiacetazone were described. A biochemical study of the digestive metabolism of ruminants was discussed. The changes which occur in the leucocyte picture and in certain blood constituents of the ewe in late pregnancy were described, and their possible relation to the adrenocortical hormones was discussed. An account was given of a method of field evaluation of sheep dips, in which an attractant solution is applied to the skin and wool of sheep at intervals after dipping, and the efficiency determined by the effect on blowflies attempting to oviposit on the wool.

Demonstrations were given of the methods used in the evaluation of disinfectants for dairy use. Disinfectants for hatching eggs were tested on eggs infected on the surface with a *Salmonella* culture. Disinfectants for dairy utensils were assessed by their effect on plate counts on standard metal strips infected with cultures suspended in milk. Field trials of dairy disinfectants under working conditions were described.

The meeting ended with a short scientific session at which papers by Dr. G. F. Somers on "The Assay of Adrenaline in Creams", and by Dr. P. W. Muggleton on "The Standardization of Pertussis Vaccine" were read and discussed. The chairman of the Group, Dr. H. O. J. Collier, expressed the appreciation of the members to Mr. W. A. Broom and his colleagues for organizing the meeting.

TRANSPARENT CONDUCTING FILMS OF GOLD

In an article in *Nature* describing recent work in the Light Division of the National Physical Laboratory, Teddington, on methods of producing transparent electrically conducting films on glass[1], the films then mentioned were oxide films; and, although the conductivity of some, especially tin oxide, had been abnormally enhanced by special treatment, the *modus operandi* is not yet fully understood. One object of the work was to provide means for heating the glass electrically; but it was noted that the resistance of the films was rather high, making necessary the use of voltages of some hundreds for the effective de-icing of coated aircraft windows in adverse conditions.

A further investigation has rapidly followed this, by the same workers, and with the same practical aim. The results are noteworthy because they touch upon a rather different field of research. It has long been known that metallic films, made by no matte what process, almost always have a much greate resistivity than the bulk metal, even after allowanc for an expected increase due to the thinness of th films. This discrepancy between observed an predicted resistivities is assignable to the differenc between the granular or non-coherent structure o the actual films, and the homogeneous plane-paralle model assumed in the theory.

The starting-point of the new investigation was study of the influence which the condition an material of the substrate might have upon th properties of superposed gold films. For example, gold film laid down on glass cleaned with dry pre cipitated chalk was found to have a resistivity les than half that of similar films on glass cleaned b more ordinary methods, while the colour of the fil was a dull yellowish-green instead of the familia bluish-green. These experiments were made wit gold films about 70 A. in thickness, laid down unde strictly controlled conditions by cathodic sputtering Similar films were then laid down on glass freshl coated with substrate films of various oxides, als made by sputtering. In some such cases, especiall with substrates of the oxides of cadmium, lead, bismut and zinc, the properties of the gold film were eve more strongly modified. Films on zinc oxide were always blue, with almost infinite resistance. Films 70 A. in thickness (on a weight–bulk density basis) on bismuth oxide were, however, of a pale-straw colour, and had a resistance of about 15 ohms between opposite edges of a square sample. The transmission factor for white light was about 70 per cent. On heating such a sample to 200° C. for a few minutes the colour became paler still, the transmission factor rose to about 73 per cent, and the resistance dropped to about 10 ohms. Moreover, these results were very closely reproducible from sample to sample. For comparison, it is to be noted that a similar film on glass cleaned by ordinary methods would be blue-green in colour, and have a transmission of about 35 per cent and resistance of unpredictable value in a range of roughly 80–200 ohms.

It is further of interest to note that, with these ilms of gold on a substrate of oxide, the transmission can be further enhanced by using various methods analogous to 'blooming'.

For the moment, the structure of the highly conducting films is a matter of speculation but is being mmediately investigated. It is, however, remarkable hat the resistance value obtained is very close to the heoretical value for a plane-parallel lamina having he same weight of gold per unit area as the actual ilm. It seems also that the low optical absorption may be consistent with the optical constants for gold n bulk, with some form of 'thinness' correction, hough this has not yet been fully investigated.

Whatever film-structure may be revealed by further xamination, this work appears to offer an interesting ew field for the study of surface forces and states, s well as providing for practical applications a ransparent film of a novel type and exceptionally ow resistance. It is understood that the Ministry of upply, for which the research is being undertaken y the National Physical Laboratory, is actively ngaged in studying the problems of producing and sing windows having a coating of this double-layer lm.

Nature, **169**, 829 (1952).

HOMING ABILITY IN BIRDS

A RECENT issue of *Ibis* contains two important articles on the direction-finding abilities of irds (94, No. 2).

In the first article G. V. T. Matthews describes an xtensive series of homing experiments carried out ith 249 lesser black-backed gulls (migratory species) nd 91 herring gulls (a restricted nomad), together ith twenty other sea birds. On release the lesser lack-backed gulls showed a significant homeward rientation which was absent when the sun was bscured by clouds; some direct evidence and an nalysis of the homing success indicated that a large roportion of the gulls were homing by an inefficient method, probably random exploration for known isual landmarks. A minority, however, were homing y a method not dependent on the distance or area f release, the orientation behaviour suggesting some orm of sun navigation. The herring gulls showed a much lesser ability to 'home', and this could be xplained by there being a much smaller proportion able navigators among them. Matthews also arried out experiments in which the earth's magnetic eld was masked by airborne magnets; this in no ay affected homing ability.

In the second article Gustav Kramer describes experiments carried out with starlings and homing pigeons. The starling's ability to reproduce constant compass directions was demonstrated in two ways: first, by using migratory activity as an indicator, the bird tending to take up a constant direction; second, by training the birds to choose one of several (up to twelve) feeders symmetrically distributed around the cage. If the incidence of light were changed by use of a mirror arrangement the direction chosen by the bird changed correspondingly. The sun was shown to be a governing factor, the orientation faculty (in experimental conditions) vanishing if the sun were hidden. The correct direction was reproduced regardless of the time of day.

Experiments with homing pigeons showed that these birds were able to home over an unknown stretch of two hundred miles. Some sort of astronomical navigation is suggested by the fact that the pigeons seemed to be orientated even before starting. Apart from this orientation method direction, learning could be produced by training the pigeons along one homing line; by displacing the bird sideways they are misled, this being taken as the test of direction learning.

Like starlings, pigeons were trained to choose food from a definite direction under experimental conditions, and here again the sun was the physical clue for orientation.

BRITISH COAL UTILIZATION RESEARCH ASSOCIATION

REPORT FOR 1951

WITH an annual fuel crisis tending to become an accepted feature of British life, means of increasing the output of coal from all indigenous sources have been widely publicized and implemented, so that coal production has been rising steadily during recent years. The nation's fuel problem remains, however, for coal consumption has also increased, so that now a gap exists between demand and supply which will doubtless widen unless and until coal is used more wisely and far more efficiently than at present. It is gratifying to note, therefore, that the resources of the British Coal Utilization Research Association are being devoted to bringing "in our time" a real improvement in the efficiency of using coal in all its conditions of availability.

Progress towards that aim is described in the annual report of the Association[*], which was presented by the president, Sir Charles Ellis, to the annual general meeting on May 7. The many investigations being pursued include a new method of conditioning slurry, the automatic control of coal-fired gas producers, the reduction of smoke from domestic open fires, and the use of coal for chemical purposes.

Several million tons of wet coal slurry are produced each year in colliery washeries. As produced, the slurry is a water-logged aggregate which, even after dewatering, is too finely divided to burn satisfactorily. If it could be converted into a usable form, however, this material would make a substantial contribution to the nation's fuel supplies. A pelleting process has now been devised in which the slurry, pre-treated to form a wet mud, is first broken up and then agglomerated into spherical particles of either $\frac{1}{8}$–$\frac{1}{4}$ in. or $\frac{1}{4}$–$\frac{3}{8}$ in. diameter. The pelleting device is simple; the pellets themselves, when dried, are strong enough to withstand moderate handling, and have been burnt successfully on a mechanical stoker plant and do not disintegrate in the fuel bed of a gas producer.

---

[*] British Coal Utilization Research Association: Annual Report for 1951. Pp. 52. (Leatherhead: the Association, 1952.)

The work on the automatic control of gas producers is aimed at improving practice in respect of the coal-fired producer so that coal may compete more favourably with imported oil as a fuel for the steel and glass industries. Two systems of control of the coal feed to gas producers have now been developed which maintain, under conditions of variable load, a constant quality of the gas. In one, which is recommended for use in steelworks, the rate of coal feed is linked directly to the rate of air feed to the producer. In the other, which is simpler, the controller is operated by the gas off-take temperature, and is to be preferred for use in the glass industry. A recent development of the former system is the use of blast steam pressure as the main controlling variable instead of air flow.

The ever-present problem of smoke emission is being studied in four different ways, namely: an investigation of the factors affecting the release of smoke from burning coal; the destruction of tar vapours in smoke; the possibility of reducing smoke formation by chemical pre-treatment of coal; and reduction of smoke by modified appliance design. Work on the first three problems is still in its early stages. Modifications to the design of domestic open fires have led to reduced smoke emission, but only under such rigid control as cannot yet be obtained under normal home conditions.

Although the work of the Association is concerned primarily and inevitably with the use of coal as a fuel, the possibility of coal replacing oil as a source of essential chemical substances in the future has not been overlooked, and a first method of attack by solvent treatment is being made.

The work of the Association as a whole must be regarded as of great value to a country the economy of which is based on coal, and it is to be hoped that circumstances will permit of its future expansion and acceleration.

WILD LIFE IN ARABIA

OPEN plains, scorching and shadeless during the summer, windswept and freezing during the winter night, present a hard environment. Yet up to the beginning of the present century an interesting assemblage of animals existed in the Arabian desert. Even when modern rifles came into general use the species held their own to a satisfactory extent. But the last decade has witnessed the advent of a mechanized predator, the 'jeep', and, according to a recent article by Desmond Foster-Vesey-Fitzgerald, it cannot be long before motorized hunting parties will sweep Arabia's fauna away (*Oryx*, 1, No. 5; April 1952).

It may be of value, therefore, to record the status of some of the more interesting animals during recent years. The Arabian oryx is now extinct in the northern sands of the Great Nafud. Some interesting pictures of this species have been scratched by idle shepherds on sandstone outcrops in the vicinity of Hail. In the southern sands of the Rub Al Khali the oryx still exists.

Three species of gazelle are still widespread and reasonably numerous. The northernmost species is Loder's gazelle, the 'rhim' or the Arab (*Gazella leptoceros marica*), which inhabits the gravel plains, limestone plateaux and sands of Central Arabia. This is a gazelle of the steppe where perennial dwarf shrubs are supplemented by abundant annual herbage following winter rains. It is a stocky, whitish animal which congregates in large flocks composed of fifty to a hundred individuals. It has not been observed to leap or bound like the other species, but travels nevertheless at a deceptively fast speed. The 'rhim' is the only species found on the northern gravel plains and along the fringes of the central Arabian sands, being especially abundant on the Bisaita plain and Teisiya plateau. It extends southwards into the tropic, where it has been observed congregating with the other species.

The other two species, the dorcas gazelle (*Gazella dorcas saudiya*) and the Arabian gazelle (*Gazella gazella arabica*) are both graceful reddish animals which leap and bound in a manner quite unlike the 'rhim'.

The dorcas gazelle or 'afri' appears to be confined to those parts of the interior of the peninsula where *Acacia* grows. It ranges widely over the great gravel plains which lie to the east of the Hejaz mountains but is only encountered in very small parties or alone.

The Arabian gazelle or 'idmi' is also a gazelle of *Acacia* country and appears to be the common species of the coastal plains. But it also occurs on the highland plains of the interior with the dorcas gazelle and is, in fact, the commonest species in all the country to the east of Taif.

Gazelle in Arabia never drink and they are able to exist without green herbage or dew. It must be presumed that the necessary moisture for their welfare is obtained from buds of perennial plants which, although encased within dry scales during drought periods, remain viable and ready to burst as soon as rains fall. Probably the most important plant in this category for the 'rhim' is the dwarf shrub *Rhanterium eppaposum*, and for the other species the various kinds of *Acacia*.

The ibex exists in Arabia where a suitable habitat occurs. Such places include the sandstone gorges around Medain Saleh in the Hejaz, the basalt ranges of the Jebel Shammar around Hail, and the drier mountains of Dhofar in Southern Arabia.

The wolf (*Canis lupus* var.) is still fairly common in Central Arabia, especially in the limestone country where springs are frequent and caverns provide suitable dens. The striped hyena is widespread but nowhere common, although tracks are often seen on the Red Sea coastal plains.

The leopard is rare but exists in the Red Sea hills south of Jedda, where baboons are plentiful, and also in the more generously wooded hills of Dhofar.

In Arabia the ostrich is extinct, although it would appear that these birds existed in some numbers over the open gravel plains of the Bisaita in North Western Saudi Arabia until about twenty years ago. During the 1930's there was a big massacre in order to obtain plumes; but a few survivors lingered on until about 1944, when the last were killed. In south eastern Arabia the ostrich became extinct about sixty years ago; but fragments of egg-shell can still be quite frequently found in the Bainuna country between the base of the Qatar peninsula and the Trucial coast.

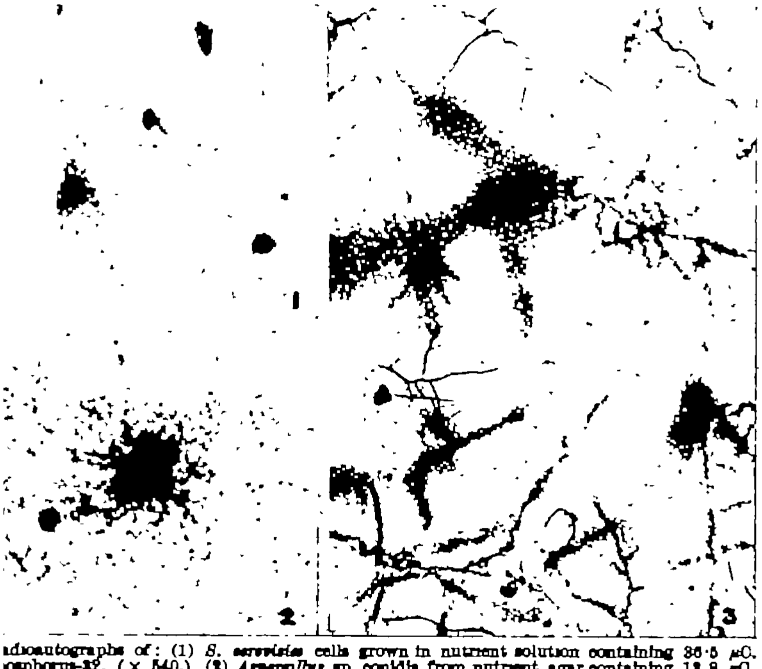
Detection of Radiophosphorus in Cells and Spores of Fungi by Radioautography

THE employment of radioautographic techniques as been of much value in botanical studies in emonstrating the presence and localization of tracer lements within plant organs and tissue. In this espect the work of Arnon *et al.*[1], Colwell[2], and Iarrison *et al.*[3], may be cited as typical. Pearson t *al.*[4] prepared radioautographs of fungus cultures, ut stated that because of the limitations of the aterials and methods employed it was not possible o obtain radioautographs of single cells or hyphæ. oyd *et al.*[5], however, were able to obtain single cell utographs of leucocytes and erythrocytes. More ecently, Fitzgerald *et al.*[6], using tritium, obtained adioautographs of single yeast cells and *Paramecia*.

In the method employed here, phosphorus-32 was dded to the nutrient medium in the form potassium lihydrogen phosphate. *Aspergillus* sp., *Hormodenrum* sp. and *Penicillium* sp. were grown on nutrient gar ('Difco') containing 5 per cent glucose. *accharomyces cerevisiae* was grown in nutrient broth 'Difco') containing 5 per cent glucose. Cells harvested rom these media were washed and placed directly pon the surface of a photographic emulsion. Best esults were obtained with a special emulsion (*NTB* lates) developed by the Eastman Kodak Research aboratories, Rochester, N.Y. After exposure, the lates were developed in a 'fine grain' developer.

The accompanying photographs are from representtive radioautographs obtained in this work. It eems of interest to note that localization of activity ccurred not only in mycelium but also among conidia rom the same test-tube culture, some producing radioautographs and others not. Perhaps conidia of different ages vary in their phosphorus content. A like condition was noted among cells of *S. cerevisiae* from a single broth culture. This is in agreement with the results of Boyd and Levi[7], who reported finding evidence of non-uniform uptake of phosphorus-32 by yeast cells.

This work was conducted in the Department of Botany, McMaster University, Hamilton, Ontario.



adioautographs of: (1) *S. cerevisiae* cells grown in nutrient solution containing 36·5 μC. osphorus-32. (× 540.) (2) *Aspergillus* sp. conidia from nutrient agar containing 13·8 μC. osphorus-32. Exposure period, 14 days on Kodak *NTB* emulsion. (× 540.) (3) *Penicillium* . mycelium from a nutrient solution containing 250·0 μC. phosphorus-32. Exposure period, 30 days on Kodak *NTB* emulsion. (× 120)

Effect of Œstradiol Benzoate and Orchidectomy on the Toxicity of Trypan Blue

PRIBELKOV[1] found that the toxic effect of trypan blue was manifested in guinea pigs by loss of weight and hair, apathetic appearance, fall in hæmoglobin content, accumulation in the blood of large numbers of polychromatophiles and normoblasts and the appearance of erythrocyte decomposition products in many organs. Nicol[2] pointed out that some animals appeared to be more susceptible to the toxicity of the dye during œstrus. The toxic effect of injections of trypan blue on the tissues has been studied histologically by Downey[3], who observed that the cells of connective tissue first showed diffuse staining of the cytoplasm and the nucleus which he considered to be the appearance of dying cells. Many cells died, but some were able to eliminate the dye and recover, except the eosinophiles. The reticulo-endothelial cells, which specifically store the vital dye, are affected in the same manner, and it is probable that the resulting inhibition of the functional capacity of the reticulo-endothelial system is partly responsible for the toxic manifestations of trypan blue.

In view of the stimulating effect of œstrogens on the reticulo-endothelial system[2,4], it was considered desirable to ascertain their influence on the toxicity of trypan blue.

In the present experiments, the toxicity of trypan blue, judged by the mortality-rate and by the effect on body-weight, was studied in ninety guinea pigs, all of which received one daily subcutaneous injection of trypan blue for six days. The daily dosage of the dye was calculated on the basis of 0·8 ml. of a 1 per cent solution in distilled water per 100 gm. body-weight. The animals were weighed immediately before the first and after the last injection of trypan blue. They were divided into three groups: 30 intact males, 24 orchidectomized animals and 36 ovariectomized animals. Each group included animals which received only the dye injections and therefore served as controls, and also animals which received one daily intramuscular injection of 0·5 mgm. œstradiol benzoate for one to four weeks, during the last six days of which they also received the dye. Œstradiol benzoate was selected for the present investigations because of its low toxicity compared with other œstrogens[6].

Results in intact male animals. Trypan blue was responsible for the death of one out of seven animals not given hormone, and one out of twenty-three animals treated with hormone. The changes of weight observed after the course of trypan blue injections averaged a loss of 6·5 per cent in seven animals not given hormone, a loss of 6·2 per cent in six animals given œstradiol benzoate for one week, a loss of 0·9 per cent in six animals given œstradiol benzoate for two weeks, a gain of 1·9 per cent in five animals given œstradiol benzoate for three weeks and a loss of 1·3 per cent in six animals given œstradiol benzoate for four weeks.

To ascertain to what extent these changes of weight were due to the trypan blue, five intact animals were given one daily intramuscular injection of 0·5 mgm. œstradiol benzoate for four weeks and were not given trypan blue. They were weighed regularly at weekly intervals. No animals died as a result of the hormone treatment. The average weekly change in body-weight in these animals was a gain of 2·4 per cent during the first week, a gain of 1·8 per cent during the second week, a gain of 1·9 per cent during the third week and a gain of 0·8 per cent during the fourth week. The gain in weight is probably due to the water-retaining power of the œstrogen[6].

Comparison between the changes of weight produced by trypan blue alone, by the hormone alone and by the hormone together with the dye indicates that the œstrogen conferred a certain degree of immunity against the toxicity of the trypan blue, and that this immunity was most marked in the animals which received the œstrogen for three weeks.

Results in orchidectomized animals. Trypan blue was responsible for the death of one out of ten animals not given hormone and two out of fourteen treated with hormone. The changes of weight observed after the course of trypan blue injections averaged a loss of 5·6 per cent in ten animals not given hormone, a loss of 1·3 per cent in four animals given œstradiol benzoate for one week, a gain of 2·3 per cent in three animals given œstradiol benzoate for two weeks, a gain of 6·4 per cent in two animals given œstradiol benzoate for three weeks and a gain of 5·1 per cent in five animals given œstradiol benzoate for four weeks.

Comparison between the above changes of weight in the orchidectomized animals and those in the intact animals shows that the toxic effect of trypan blue was less in the orchidectomized than in the intact animals, and indicates that orchidectomy adds to the protective influence of the œstrogen.

Results in ovariectomized animals. Trypan blue was responsible for the death of two out of twelve animals not given hormone, and four out of twenty-four treated with hormone.

The changes of weight observed after the course of trypan blue injections averaged a loss of 5·9 per cent in twelve animals not given hormone, and a loss of 3·5 per cent in twelve animals given œstradiol benzoate for one week, while in twelve animals given œstradiol benzoate for two weeks practically no change in weight occurred. The results, therefore, show that œstradiol benzoate reduced the loss in weight produced by the toxic effect of the dye.

The protective influence of œstradiol benzoate against the toxicity of trypan blue, observed in all the groups of animals, may be attributed to its stimulating effect on the reticulo-endothelial system, which thus becomes more capable of dealing with the dye and detoxicating it. The effect of orchidectomy may be explained by a similar stimulating influence on the reticulo-endothelial system.

Antagonistic Effects of Cortisone and Salicylate

THE injection of cortisone has been observed to cause glycosuria in normal rats fed on a high carbohydrate diet[1]. Sodium salicylate reduced this glycosuria (Fig. 1) and also reduced the hyperglycæmia obtained in these animals after feeding (Fig. 2).

The changes in the liver glycogen content of adrenalectomized rats produced by cortisone in the presence and absence of salicylate were also studied. The rats were maintained on 0·5 N saline and a normal diet for four days after operation. Forty-eight adrenalectomized rats were divided into seven groups, three of these groups, each containing six animals, being killed at 0, 4 and 6 hr.; two groups were injected with 5 mgm. of cortisone per rat at 0 hr. and killed at 4 hr. (seven rats) and 6 hr. (eleven rats), respectively; and in two further groups of six animals each rat received 5 mgm. of cortisone and 100 mgm. of sodium salicylate at 0 hr., one group being killed at 4 hr. and the remaining group at 6 hr. The animals were fasted during

Time of sacrifice (hr.)	Liver glycogen content (gm./100 gm. wet wt.) with standard deviations					
	Untreated	No. of rats	Treated with cortisone	No. of rats	Treated with cortisone/salicylate	No of rats
0	2·33 ± 0·55	6				
4	1·77 ± 0·81	6	3·30 ± 2·90	7	0·50 ± 0·12	6
6	1·45 ± 0·7	6	3·91 ± 1·99	11	0·60 ± 0·2	6

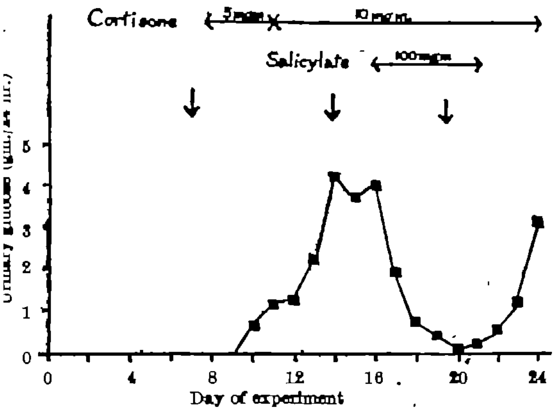

Fig. 1. Mean 24-hr. urinary glucose for a group of four normal rats fed on a high carbohydrate diet and injected with cortisone and sodium salicylate. Cortisone: 5 or 10 mgm. as saline suspension of cortone acetate (Merck) daily; sodium salicylate: 100 mgm. in 1 ml. arachis oil daily. The arrows indicate the days on which the blood sugar curves in Fig. 2 were obtained

he experiment. The glycogen content of liver vas estimated by the method of Good, Kramer and omogyi[2], and the results are shown in the accompanying table.

Comparison of these results showed that salicylate, n the presence of cortisone, caused significant deple- ions of liver glycogen at 6 hr. compared with both he group treated with cortisone ($P = 0·01$) and the ntreated group ($P = 0·01$). Cortisone produced a ignificant deposition of liver glycogen at 6 hr. $P = 0·1$) when compared with the initial value at) hr. Salicylate therefore not only caused breakdown f existing glycogen but also prevented the formation f new glycogen by cortisone.

These antagonistic effects of salicylate and cortisone ire of interest for two reasons. First, it has been uggested that the therapeutic activity of salicylates s mediated by the pituitary and adrenal cortex, eading to the production of adrenal corticoids[3]. If his hypothesis is correct, then salicylates and adrenal orticoids, of which cortisone may be considered a ypical example, should have the same general effects n the tissues. Secondly, salicylates have been ob- erved to reduce the glycosuria and blood glucose of lloxan-diabetic rats[4]; in these animals there is ncreased gluconeogenesis due to the action of adrenal orticoids, and an inhibition of this process by salicylates may provide at least a partial explanation of these effects.

Effect of Tissue Cultures of Maize Endosperm on the Growth of Excised Maize Embryos

IN 1947, LaRue reported the regeneration of sporophytes from maize endosperm tissue, and also limited growth of the endosperm tissue without regeneration or differentiation when excised and placed on an appropriate artificial medium[1]. In 1948, continuing this study, he succeeded in obtaining a culture of maize endosperm of a callus-like nature having unlimited growth[2]. This original stock has been in culture for more than two years, and I also have stocks in culture from two other varieties of maize.

Ziebur and Brink reported in 1951 the stimulative effect of freshly excised *Hordeum* endosperms on the growth of immature plant embryos *in vitro*[3]. It was thought of interest to study the effect of cultured endosperm tissue on the growth of freshly excised maize embryos of various ages to observe whether or not it would still function as a nutrient endosperm for the embryos[4]. A preliminary experiment has therefore been carried out at the University of Michigan.

The cultured maize endosperm tissue employed in this experiment was that of LaRue's original stock. This tissue has been found to grow well only on a basal medium supplied with certain additional substances. White's basic medium plus tomato juice has been used for obtaining good growth.

The embryos were placed directly upon (1) White's basic medium, (2) White's plus tomato juice, and on masses of maize endosperm tissue from culture which had been transferred previously to (3) White's and (4) White's plus tomato juice. Embryos were also placed on masses of crown gall tumour tissue growing on (5) White's and (6) White's plus tomato juice medium. The results, recorded after five days, are given in the accompanying table. Growth is indicated by the plus signs and no growth by the minus signs.

Medium	16-day embryo var. 'Our Choice' 0·5–1·0 mm. length	20-day embryo var. 'Surprise' 3·0–4·0 mm. length
1	+	+ + + + +
2	+	+ + +
3	—	+ + +
4	—	+ +
5	—	+
6	—	+

1. Endosperm cultured on White's medium + tomato juice.
2. ,, ,, ,, ,,
3. White's medium + tomato juice.
4. ,,
5. Crown gall tissue growing on White's medium + tomato juice.
6. ,, ,, ,, ,, ,, ,, ,,

It is apparent from these results that the endosperm tissue in culture does improve the growth of the excised embryos. The growth of the older embryos is better than on the nutrient medium alone. It stimulates some growth of the younger embryos. Crown gall tissue does not improve growth of the embryos. It is noted that the addition of tomato juice improves the growth of the embryos on the basal medium. It may be concluded that the cultured endosperm has retained its endosperm function.

A New Technique for the Sterile Culture of Plant Embryos *in vitro*

THE two essentials for successful tissue culture are a sufficient supply of nutrients and adequate aeration. In the culture of plant embryos from an early stage of development it is also often desirable that cultures shall be suitable for microscopical examination.

The relative merits of different culture containers are discussed by White[1], and the technique here described combines the simplicity and freedom of manipulation of the flask method with ease of microscopical examination afforded by the hanging drop.

The embryos are grown on two strips of filter paper (No. 1. 4 × 1 in.) supported on a glass strip (3 × $\frac{3}{4}$ in.). This is placed in a boiling tube (6 × 1 in. 'Pyrex') containing 5 c.c. of liquid medium so that it rests nearly vertically with one end in the medium. The tubes are afterwards plugged with cotton-wool and sterilized ready for inoculation. The medium is absorbed by the filter paper and is readily available to the embryos, which are thus surrounded by a film of nutrients and also have free access to the air. If, however, the dimensions of the filter paper do not exceed those of the slide, the medium is less accessible to the embryos.

Embryos placed centrally on the slide can be examined in detail during all stages of development through a microscope with a 1-in. objective without their being removed from the tube. Tubes can be placed horizontally, or nearly so, without spilling or wetting of the cotton-wool plugs by the medium; the dimensions are such that the liquid runs down beneath the slide, and with care there is little danger of the embryos being washed out of position. Measurements can therefore be made with an eyepiece micrometer and camera lucida. In later stages of development the seedling grows in an upright position and can be measured against a scale on the filter paper or a ruler with reasonable accuracy.

Cultures are economical and easy to maintain over long periods of time. Evaporation from the tubes is low, and it has been found that a change of medium once a fortnight is satisfactory. This can be done by removing the embryos singly with forceps into a new tube, or by transferring the whole slide from one tube to another with no disturbance to the embryos.

Large numbers of samples can be maintained at any one time in a small space since tubes are easy to store, and in the early stages of development five or even ten, embryos can be grown in one tube.

It is possible that this method may prove equally satisfactory for culturing tissues other than plant embryos, where a liquid medium is required without the disadvantages of immersion.

Autonomic Ganglion Depressant Properties of Barbiturates

THOUGH the central nervous system depressant and anticonvulsant properties of the many derivatives of barbituric acid have been extensively studied, relatively little is known of their effects on the autonomic nervous system.

Depressant effects of amylobarbitone on the cardiac vagus were first described by Lieb and Mulinos[1], and have been confirmed by other workers. Depressant effects on salivary secretion were shown by Stavraky[2], for amylobarbitone, and by Emmelin[3], for hexobarbitone. It is not clear from any of this work whether the depressant effects were exercised at the autonomic ganglion or more peripherally.

Initial experiments showed that amylobarbitone sodium, administered intravenously to the cat in doses of the order of 5 mgm. per kgm., depressed ganglionic transmission without depressing the peripheral structures. By a method involving periodical electrical stimulation of the pre-ganglionic trunk of the cervical sympathetic, and recording of the contractions of the nictitating membrane, ganglion depressant effects of amylobarbitone were compared quantitatively with those of tetraethylammonium iodide; amylobarbitone was about one-quarter as potent as tetraethylammonium iodide. In a similar manner, the depressant properties of some fifteen of the commoner barbiturates were compared with those of amylobarbitone. The accompanying table shows the results obtained with a few of the more interesting derivatives.

Barbiturate (as sodium salt)	(*A*) Mean potency on sup. cerv. gang. ± stand. errors	(*B*) Relative anæsth potency	Ratio $\frac{A}{B}$
Amylobarbitone	100·0	100·0	1·00
Butobarbitone	99·1 ± 6·2	71·0	1·40
n-Hexylethyl	43·4 ± 2·7	69·2	0·63
Pentobarbitone	42·5 ± 1·5	163·6	0·26
Hexobarbitone	31·7 ± 2·9	186·2	0·17
Barbitone	17·1 ± 1·3	23·1	0·74
Phenobarbitone	14·2 ± 0·6	40·3	0·35
Thiopentone	12·8 ± 1·2	450·0	0·03

The first two columns show: (*A*) mean ganglion depressant potencies determined from a number of experiments, and (*B*) relative intravenous anæsthetic potencies (calculated from data of Butler[4]). The figures are expressed in terms of amylobarbitone, which has been allotted the arbitrary figure 100·0 in each instance. It is interesting to note that, for the different drugs, ganglionic and anæsthetic potencies show no direct correlation one with the other; amylobarbitone and butobarbitone show the highest activity on the ganglion and thiopentone the lowest. Pentobarbitone, which is isomeric with, and more otent an anæsthetic than, amylobarbitone, shows n activity of only 42·5 on the ganglion. The relationhip between ganglionic and central nervous deressant activities is expressed in the third column s the ratio *A*/*B*. The highest ratio (1·40) is given y butobarbitone.

Other barbiturates, which are not in current clinical se, are now being investigated with the view of letermining the structure – action relationships reponsible for conferring increased ganglion depressant ffects.

Rigid-Body Motions in Special Relativity

The rigid-body motions proposed by Born[1] and Herglotz[2] have, in general, only three degrees of freedom, so that the world line of one point determines the complete motion. My purpose here is to define a group of rigid-body motions with six degrees of freedom as in Newtonian mechanics. Any such definition must be regarded as tentative, and its physical significance tested by experiment (see following communication from Prof. J. L. Synge).

In the space-time of Minkowski, where a point has the four co-ordinates x^1, x^2, x^3, x^4 ($= ict$), let a world line be determined by the equations:

$$x^r = a^r + b_1\mu_1{}^r + b_2\mu_2{}^r + b_3\mu_3{}^r + b\lambda^r, \quad (r = 1, 2, 3, 4). \tag{1}$$

Here a^1, a^2, a^3 are three arbitrary functions of a parameter u, and $a^4 = icu$; λ^r is the unit 4-vector in the direction of the da^r/du; $\mu_1{}^r$, $\mu_2{}^r$, $\mu_3{}^r$ form an orthonormal triad of 4-vectors orthogonal to λ^r, which triad may be specified by three arbitrary functions of u giving, say, its Eulerian angles; b_1, b_2, b_3 are constants and $b = (b_1{}^2 + b_2{}^2 + b_3{}^2)^{1/2}$. By letting b_1, b_2, b_3 have a range of values, we get a congruence of world lines depending on six arbitrary functions of u. If a body moves so that the world lines of all the particles form such a congruence, then we shall say that the body has a rigid motion.

The curve $x^r = a^r$ is the history of the particle for which the b's vanish; this particle, which takes a special role, may be called the 'drag-point'. Since $a^4 = icu$, the parameter u may be interpreted as the time along the world line of the drag-point.

The connexion with Newtonian rigidity and the Lorentz contraction may be seen as follows. If x^r and y^r are two events of the congruence with the same value of u, then the invariant $(x^r - y^r)(x^r - y^r)$ with r summed, which is the square of the Minkowski distance, is independent of u and therefore remains constant throughout every rigid motion. The value of $\lambda^r(x^r - y^r)$ also remains constant. This latter condition implies that whenever the body, initially at rest, is accelerated and finally moves in uniform translation, it is shortened in the direction of motion by the Fitzgerald–Lorentz contraction factor.

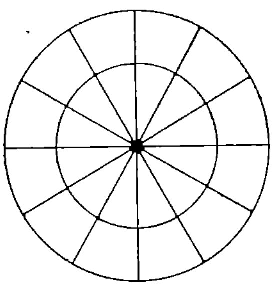

Fig. 1

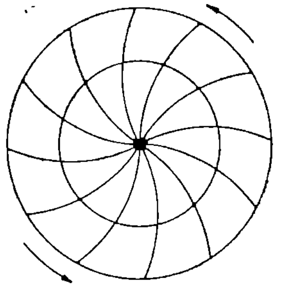

Fig 2

The following example of rigid motion is a relativistic analogue of the Newtonian rotating disk. Choose for the drag-point the origin of a Galileian observer S so that a^1, a^2, a^3 are all zero. For the rotating triad take $\mu_1{}^r = (\cos\theta, \sin\theta, 0, 0)$, $\mu_2{}^r = (-\sin\theta, \cos\theta, 0, 0)$ and $\mu_3{}^r = (0, 0, 1, 0)$, where θ is some function of u. With b_3 equal to zero, equations (1) give the motion of all points in the x_1, x_2 plane, the first and second derivatives of $\theta(u)$ representing the angular velocity and angular acceleration of the body respectively. Fig. 1 shows the disk at rest in S with radial lines and circles about the origin etched on its surface, and Fig. 2 shows the same etchings as they appear to S when the disk has acquired a constant angular velocity ω, drawn for the case when the peripheral velocity is $\frac{1}{2}c$. The straight radial lines become curved with polar equation $r\omega = c(\theta + \text{constant})$. The radii of the circles remain the same, as indeed is true even in non-uniform angular motion.

Gardner's Hypothesis and the Michelson–Morley Experiment

When Gardner's hypothesis (see preceding communication) is applied to the Michelson–Morley experiment, performed with an interferometer with horizontal rigid arms, carried on the rotating earth, it yields the following formula for fringe-shifts if we take the drag-point to be the centre of the earth:

$$\delta/w = (D/\lambda)(E/c)\,\varphi \sin 2\theta.$$

Here δ is the fringe-shift, w the fringe-width, D the arm-length of the interferometer, λ the wave-length used, E the velocity of the earth's surface due to the earth's rotation alone, c the velocity of light, φ the deviation of the plumb line, and θ the azimuth of the telescope arm, from the north eastward. If, on the other hand, the drag-point is near the interferometer, the predicted fringe-shift is below the limits of observation.

In a set of experiments involving a very great number of observations, D. C. Miller[1] observed fringe-shifts resembling those predicted by the above formula, which reads, when we insert the numerical values appropriate to Miller's experiments:

$$\delta/w = 0{\cdot}23 \sin 2\theta.$$

The theoretical amplitude is about four times that observed by Miller; but the variation as sin 2θ is like that which Miller found, for the harmonic analysis of his results gave a strongly predominant term with period 180°, and the azimuths giving maximum shift showed a fairly strong preference for the north-easterly quadrant; indeed, his observations of June 1, 1925, give an average azimuth of 42°, to be compared with the value of 45° given by the above formula. A small shift with period 360°, on the existence of which Miller insisted, can be explained by a slight inclination of the arms to the horizontal, which yields terms in sin θ and cos θ, omitted from the above formula for the sake of simplicity.

The positive results obtained by Miller have long remained an anomaly because experiments by Joos[2], Kennedy[3], Illingworth[4] and Michelson (with collaborators)[5] gave essentially null results. I suggest as a possibility that the discrepancy between these results and those of Miller may be found in the mountings of the interferometers. Joos supported his instrument on springs and so insulated it mechanically from the earth; the others used flotation on mercury, as did Miller, but Miller used a substantial pin attached to the interferometer and passing loosely through a bearing. This pin is shown by Miller (Fig. 5, *loc. cit.*, p. 208), and I am much indebted to Prof. R. S. Shankland, of the Case Institute of Technology, for further information obtained from the mechanic who worked with Miller.

Although the pin was far from attaching the interferometer rigidly to the earth, it may have provided sufficient constraint to make the interferometer behave, at least partially, as though it were part of the earth itself, and so give us an excuse for taking the earth's centre as drag-point (the most natural point, surely, if we were dealing with the earth itself as a rigid body).

However that may be, the concept of rigid-body motions is important in physics and an adequate theory of these motions is most desirable. It is true that we have the Born–Herglotz theory; but I have been unable to see how that theory leads to any definite prediction regarding the Michelson–Morley experiment performed on the rotating earth. Now that the special theory of relativity is firmly established, we should look on experiments like the Michelson–Morley experiment as experiments on rigid bodies rather than on light propagation. But as a test of Gardner's hypothesis, an interferometer with horizontal arms is very inefficient. When the arms are tilted up, the theory predicts quite a large effect with period 360° in azimuth. Indeed, with one arm inclined to the vertical at 45° and the other horizontal, Gardner's hypothesis predicts a fringe-shift of a full fringe-width with an arm-length of only 20 cm., provided, of course, that the interferometer is firmly mounted on a vertical axis to ensure that it may be regarded as part of the rotating earth and so have the earth's centre as drag-point.

A fuller account of this work will appear in the issue of the *Scientific Proceedings of the Royal Dublin Society* commemorating the centenary of the birth of George Francis Fitzgerald.

Solar Outbursts at 8·5-mm. Wave-length

Sudden large increases in solar radio radiation, characterized by a rapid rise in intensity and a slower fall and usually associated with chromospheric flares, have been observed in the last few years by Hey[1] and others at all frequencies at which solar radiation has been measured, except at the highest frequencies. We can now report the measurement of several outbursts at a frequency of 35,000 Mc./s., or 8·5-mm. wave-length.

In the spring of 1951, a radiometer operating at a wave-length of 8·5 mm. was put in operation at the Naval Research Laboratory, Washington, D.C., and adjusted to follow the sun during the daylight hours and record continuously the intensity of the sun's radiation. Previous work at a wave-length of 8·5 mm.[2,3] had shown that the intensity of the sun's radiation at this wave-length was much more constant than at longer wave-lengths. However, the previous work was done with a highly directive beam, so that only a portion of the surface of the sun was observed at one time.

The radiometer used in the present experiment has an antenna of 24-in. aperture and beam-width of 1·1°; hence the sun is seen as a point source. The object of the experiment was to watch for sudden

ıanges in the intensity of the radiation and to orrelate these changes with those observed at cm. wave-length in a similar apparatus at this boratory, with changes observed at longer ave-lengths at other institutions, and with visual bservation of solar flares.

During the period May 1–October 1, five bursts f radiation were found with the 8·5-mm. wave-ngth apparatus. The times of occurrence of four f the bursts coincide with observed flares, and at ıe time of the fifth, May 21, 1951, 12h. 48.1m. U.T., ıere was an active region on the west limb of the un. Details are given in the accompanying table, where the 8·5-mm. bursts are shown along with ata on known bursts at other wave-lengths associated with the same occurrence. The position and time of he associated flare and the time of the associated udden ionic disturbance (S.I.D.) are given. We are ndebted to Miss H. Dodson of the University of Iichigan, to the High Altitude Observatory, Cornell Jniversity, and to the National Bureau of Standards or making available data used in this table.

The character of the bursts at 8·5 mm. is illustrated n the accompanying record, which is a tracing of he recording milliammeter in the output of the adiometer. Tracings for five outbursts are shown. Zero is at the level of sky noise. Variations in level rom day to day are due more to changes in the gain of the receiver than to variations in the solar lux. The width of the trace is indicative of the nherent fluctuation level in the instrument. The burst of May 18 had a time of rise comparable with he time constant of the instrument, 1 sec., whereas he burst of May 8 rose to full amplitude in about min. The times of rise of the other bursts fall between these two extremes. The steadiness of he trace is affected by the presence of clouds. This is most clearly shown in the trace of June 19, where the small rise preceding the burst was due o a change in cloud cover. The 8·5-mm. bursts differ from those at longer wave-lengths in two principal respects: the burst is in general of much shorter duration and the amplitude is much smaller. The largest burst yet observed on a wave-length of 8·5 mm. caused an increase in the total solar adiation of only 27 per cent. The duration of the bursts has all been less than 5 min.

Observation of bursts at very short radio wave-engths is of interest since presumably the escaping adiation comes from deeper layers of the sun's atmosphere than it does for the longer wave-lengths[3]. The observation of two types of outbursts, one when the time of onset is nearly the same for different wave-lengths, as in the burst of June 19, and the second when the time of onset occurs at later times for longer wave-lengths, has been reported before by several observers[4-9]. The single observation reported here of simultaneity of occurrence at two wave-engths, 8·5 mm. and 3 cm., is significant in that for this occurrence a transport of material[4-6,8] as the source of burst energy is highly improbable.

A New Molybdenum Carbide

STUDIES of the products formed by carburizing molybdenum with carbon monoxide have confirmed the existence of Mo$_2$C (β-phase) and MoC (γ-phase), the latter having the tungsten carbide (WC) structure. But in addition to these two phases, a new carbide (called here the γ′-phase) has been found. The X-ray diffraction lines of this new carbide have not been reported by earlier investigators.

When the carburization takes place at low temperatures, the γ′-phase is the first to be formed after the β-phase. If the γ′-phase is kept at sufficiently high temperatures, either in a stream of carbon monoxide or in vacuum, it transforms (fairly rapidly above approximately 800° C.) into the γ-phase. At high temperatures the γ-phase is evidently more stable than the γ′-phase. The γ-phase may also be the more stable of these two phases at low temperatures, although the speed of the transformation $\gamma' \rightarrow \gamma$ is then very low.

The γ′-phase is hexagonal and the unit cell contains 4 molybdenum atoms. In the accompanying table its dimensions are compared with the dimensions obtained (in our carburization experiments) for the β- and γ-phases.

	β, Mo$_2$C	γ′	γ, MoC
a (A.)	3·002	2·932	2·898
c (A.)	4·724	10·97	2·809
c/a	1·574	3·742	0·9 9
Mo per unit cell	2	4	1
Vol. per Mo (A.^{3})	18·44	20·42	20·42

The space-group is $C6/mmc$ and the molybdenum atoms occupy the position $4(f)$ with $x = \frac{1}{8}$. If the three projections of these positions on the basal plane are designated by A, B, and C, the molybdenum lattice can be symbolized by the sequence $AABBAABB$ . . . . In the β-phase (hexagonal close-packed molybdenum lattice) the sequence is $ABAB$ . . . and in the γ-phase it is $AAAA$ . . . . In this respect the molybdenum lattice of the γ′-phase forms an intermediate stage between the β- and γ-phases. However, no indication of a stacking disorder has been found.

The parameter x seems to be very close to $\frac{1}{8}$. This is remarkable, as the distance between layers A and B is then equal to the distance between layers A and A. One would expect the former to be smaller.

No signs of definite positions of the carbon atoms have been found. The composition of the γ′-phase could not be based on analyses as the entirely pure phase was never obtained. A comparison of the lengths of the c axes and the volumes per molybdenum atom of the three phases indicates that the carbon content can scarcely be less than that corresponding to the formula MoC. The fact that the transformation $\gamma' \rightarrow \gamma$ takes place without any other changes in the powder photographs suggests the formula MoC.

A metal lattice similar to that of the γ'-phase has been found by Kiessling[1] for the tungsten boride, W_2B_5. In this case the parameter z is slightly different from $\frac{1}{8}$, namely, 0·139.

A detailed report will be published elsewhere.

Preparation and Magnetic Susceptibility of an Oxygen Clathrate Compound

DURING attempts to prepare samples of β-quinol by the method of Powell and Riesz[1], we observed that the crystals obtained, which gave X-ray powder photographs characteristic of β-quinol, effervesced when dissolved in water. When 1 gm. of a sample of this substance which had been dried *in vacuo* was dissolved in water, 7·9 c.c. (at N.T.P.) of a gas were evolved. This gas contained 28 per cent oxygen, and the rest appeared to be nitrogen. It therefore seems probable that this is an 'air' clathrate[2] compound of β-quinol in which about 12 per cent of the available spaces are filled.

This suggested that an oxygen clathrate compound might be prepared if oxidation of the quinol could be prevented. A warm saturated solution of quinol in air-free alcohol was placed in a monel metal bomb and allowed to cool slowly over a period of about 24 hr., under a pressure of 25–40 atmospheres of oxygen. Faintly yellow crystals were obtained which, when dissolved in water, evolved a gas. The volume of gas obtained corresponded in different samples to clathrate compounds in which 40–50 per cent of the available spaces had been filled. The densities of the samples were consistent with this interpretation. In one case, the gas was analysed and found to contain 97·6 per cent of oxygen.

The magnetic susceptibility of a finely powdered sample was measured, and it was found to be paramagnetic ($\chi = + 3{\cdot}31 \times 10^{-6}$ at 17° C.). Analysis of the same sample gave 39·0 per cent of the available spaces filled. Assuming the specific susceptibility[3] of quinol to be $- 0{\cdot}604 \times 10^{-6}$, this leads to a value of $\chi = + 109{\cdot}5 \times 10^{-6}$ at 17° C. for the oxygen molecules trapped in the spaces. The experimental values for χ for gaseous oxygen range from 104·5 to $110{\cdot}0 \times 10^{-6}$ at 17° C., the theoretical value[4] being $107{\cdot}7 \times 10^{-6}$. This shows that there is very little magnetic interaction between the oxygen molecules in the crystals. The magnetic behaviour of the oxygen molecules at low temperatures might well prove interesting, since they will not have the opportunity of forming loose complexes O_4 as occurs in liquid and solid oxygen. Since the concentration of oxygen molecules in these samples corresponds to gaseous oxygen at a pressure of about 40 atmospheres, the magnetic properties are easy to observe.

A method of preparing pure β-quinol containing no enclosed gases has now been devised in which a warm strong solution of quinol in air-free alcoho is seeded with a crystal of argon clathrate compound and allowed to cool in a refrigerator. Unless it is kept in a very dry atmosphere, pure β-quinol tends to revert to α-quinol.

A more detailed account of these and other measurements on clathrate compounds will appear elsewhere.

We are grateful to Mr. H. M. Powell for carrying out X-ray measurements on the samples of β-quinol and to Dr. B. Lambert and Mr. A. B. Webster for analysing the gas liberated from the oxygen clathrate compound. We thank the Department of Scientific and Industrial Research for a maintenance grant to one of us (D. F. E.).

Stabilization of Free Radicals: its Importance in Reaction Kinetics

A PREVIOUS paper[1] reported on a reaction of the radical chlorine oxide:

$$ClO + O_2 \rightleftharpoons ClO_3 \rightleftharpoons \tfrac{1}{2}\, Cl_2O_6,$$

enabling the transfer of chlorine oxide by means of addition of oxygen into the more stable chlorine trioxide and eventually, at a low temperature, into the stable chlorine hexoxide (Cl_2O_6). Similarly, the discussion[2] of the mechanism of the decomposition of ozone sensitized or catalysed by chlorine points to the fact that chlorine dioxide can also be considered as a chlorine atom stabilized by an oxygen molecule. The process $Cl + O_2 = ClO_2$ is exothermic to an extent of 1·5 kcal., and runs down practically without activation energy[3]. On examining the other cases in which the oxygen atom or molecule behaves in a similar manner, the cases of HO_2, NO and NO_2 radicals are striking. HO_2 and NO_2 are hydrogen and nitrogen atoms stabilized by an oxygen molecule, whereas NO is a stabilized complex from $N\cdot$ and $O\cdot$ and can also be transformed by addition of O_2 into NO_3.

In the mechanisms of organic pyrolyses and oxidation reactions, $R\cdot$ and $R\cdot C\cdot$ radicals are also frequently encountered, forming in the presence of oxygen $RO_2\cdot$ or $RCO_3\cdot$, or, in other cases, only with atomic oxygen $RO\cdot$ or $RCO\cdot$ respectively. In the reaction schemes they are considered to be rate-determining, fairly stable, intermediate products[4]. In their halogenated forms, these radicals behave in a similar fashion. They are characterized by all having unpaired electrons and being paramagnetic. On the other hand, radicals having even numbers of electrons do not exhibit analogous behaviour in any instance. Taking numerous other examples into account, the following rule can be established.

The paramagnetic radicals containing unpaired electrons combine with the similarly paramagnetic oxygen atoms as well as with oxygen molecules, or more generally with other paramagnetic molecules, such as nitric oxide, into more or less strongly bonded mplex radicals, thus prolonging the life of the dical.

Obviously the extent of stabilization will be a nction of the heat liberated at stabilization. The ight activation energy as well as the small heat of action results in a reversible stabilization. On the her hand, if more energy is released on association, e stabilized radical participates more sluggishly in e further process; consequently, stabilization rresponds to the slowing down of the reaction. If e energy liberated at stabilization is very great, the abilized radical may even exist as a fairly stable mpound. Nitric oxide and nitrogen dioxide can be nsidered to represent such examples.

Considering that the fate of a radical is either the ropagation of the chain by reacting with another w molecule or its destruction, stabilization can fluence the rate of reaction in different ways. If it reserves radicals which otherwise are disappearing uickly, thus saving them for the subsequent steps the process, then the stabilization increases the tal rate of the reaction.

On the other hand, stabilization of a radical may celerate the recombination of the radicals, by lowing the reaction:

$$R{\cdot}X + R = R_2 + X,$$

hich simplifies the original three-body collision to a molecular process. If this recombination removes e chain carriers from the process, it is natural that abilization should result in the diminution of the locity of the total reaction.

The variation of the rate of reaction by nitric oxide ovides a suitable illustration of reaction kinetics sed on these statements. Nitric oxide is paraagnetic and exerts—as proved by the analyses of ses hitherto investigated—an influence only on the te of chain reactions proceeding by paramagnetic dicals. This influence can be two-fold. If nitric ide is present only in small amounts, it is not able stabilize all the chain carriers having odd numbers electrons, and hence there is a greater possibility r association to occur:

$$R{\cdot}\mathrm{NO} + R = R_2 + \mathrm{NO};$$

is is equivalent to the rupture of the chain and so creases the velocity.

If, on the other hand, the concentration of nitric de is greater, it diverts the chain carriers from s association, thus resulting in a positive catalytic tion. In the sequence of reactions:

$+ R + M = R_2 + M$ (rupture of the chain)
$+ A = R' + A'$ (propagation of the chain)
$\mathrm{NO} + R{\cdot}\mathrm{NO} = R_2 + 2\mathrm{NO}$ (rupture of the chain)
$\mathrm{NO}+A=R'+A'+\mathrm{NO}$ (propagation of the chain)
$\mathrm{NO} + R = R_2 + \mathrm{NO}$ (rupture of the chain),

e activation energies of the processes diminish cording to the sequence of the equations. Conseently, a large quantity of nitric oxide preserves e chain carriers from the destruction effected other ways.

The role of nitric oxide in promoting association comes also manifest at the recombination of the drogen atoms[3]. It can be demonstrated experintally that the recombination of hydrogen atoms the presence of nitrogen oxide is far more rapid an in the case of any other three-body collision rtners. By intense cooling the product $(\mathrm{HNO})_n$ be frozen out from the reaction mixture.

In the case of stabilization not being reversible, complex radical decomposing into other constituents can only effect a decrease of the rate of reaction.

The stabilization of the free radicals is pre-eminently a catalytic process, since it modifies the reaction-rate by means of an intervening substance. We have restricted the possibility of stabilization of the free radicals to paramagnetic ones. Of course, as a consequence of the prolongation of the life of these substances possessing the greatest reactivity, the extent of the reaction increases. This requires the presence of other paramagnetic substances.

From this concept, the rule[1] is not only confined to homogeneous processes, but also may involve heterogeneous ones. The catalysing effect of paramagnetic substances lies in prolonging the life of the most reactive paramagnetic radicals. If a process takes place via free radicals containing even numbers of electrons, the paramagnetic catalysts do not exert any appreciable effect, and conversely a non-paramagnetic catalyst does not influence considerably the rate of a reaction proceeding by paramagnetic radicals. Accordingly, the extent of the surface alone cannot determine the activity of a catalyst. The number of the paramagnetic molecules on the surface is an essential factor. The most effective catalysts are mixed catalysts, in which smaller or larger groups of components have only the role of a supporter promoting the development of the virtual catalyst, the paramagnetic substance, and maintaining its activity.

These facts point to the significance of the magnetic properties of substances in chemical processes, and thus to the role of magnetochemistry in reaction kinetics.

A detailed discussion of this work will be published in English in *Acta Chimica Hungarica*.

Formation Constants of some Metal-Tropolone Complexes

THE formation constants of several metal derivatives of tropolone have been determined in order to compare the co-ordination tendency of tropolone with that of other co-ordinating groups. The order of stability of the various metal derivatives is $\mathrm{Cu^{II}} > \mathrm{Be} > \mathrm{Pb} > (\mathrm{Zn}, \mathrm{Ni}) > \mathrm{Co^{II}}$. In general, this order agrees with that found for the co-ordination compounds of ammonia[1], ethylenediamine[1,2], salicylaldehyde[1–4], salicylaldehyde-5-sulphonic acid[5], β-diketones[4,6,7], 8-hydroxyquinoline[4], 8-hydroxyquinoline-5-sulphonic acid[8], and α-amino-acids[8,9]. The metal-tropolone compounds are more stable than the corresponding acetylacetone compounds, which may be further evidence of the greater stability of five-membered chelate rings compared to six-membered rings.

Tropolone was synthesized in the manner described by Cook *et al.*[10] (found: m.p., 48–50°; $pK_D = 6{\cdot}97 \pm 0{\cdot}02$ at 30°; reported m.p., 49–50°; $pK_D = 7{\cdot}00 \pm 0{\cdot}2$ at 20°).

Formation constants were determined by the potentiometric method of Bjerrum[11] as modified by Calvin and Wilson[12]. Because of the slight solubility of these complexes in water, all titrations were carried out in a solvent containing 50 per cent dioxane by volume. Determination of the pK_D of tropolone in this medium at an ionic strength approximately equal to that existing in these solutions at the midpoint of the neutralization of excess tropolone yielded a value of 7·92. It was found that the pK_D was very sensitive to slight changes in ionic strength, so for each determination pK_D was taken directly from the titration curve and this value used in the calculation of the formation constants.

Of the six metals discussed here, it was found that three (zinc, nickel and divalent cobalt) were able to co-ordinate with three molecules of tropolone to form a singly charged anion, MCh_3^-, while the other three (divalent copper, beryllium and divalent lead) combine with only two molecules of the tropolone to form neutral species, MCh_2. This behaviour was noted earlier for hinokitiol, β-*iso*propyltropolone[13–15].

The constants were calculated from concentration data, assuming all activity coefficients to be unity.

Metal	log K_1	log K_2	log K_3
Cu(II)		7 83	
Be	8 31	6 93	
Pb(II)	7·88	5 92	
Zn	7·48	6 29	3·44
Ni	7·61	6 03	3 88
Co(II)	7·04	5·71	3·68

Co-ordination with copper was so strong that log K_1 could not be determined.

The low solubilities of the complexes of several of the trivalent metals have introduced difficulties in the determination of their formation constants. Although the formation of complexes has been demonstrated with calcium, strontium and divalent mercury, additional work is necessary to obtain accurate data.

Formation curves for the complexes are shown in Figs. 1 and 2.

Crystalline material was obtained in several instances by partial evaporation of the solutions after titration. The cobalt derivative was a lustrous, reddish violet, and the zinc solution yielded light yellow octahedra. The copper compound was found to decompose at *c.* 300°, whereas the other two compounds were unaffected at temperatures up to 275°.

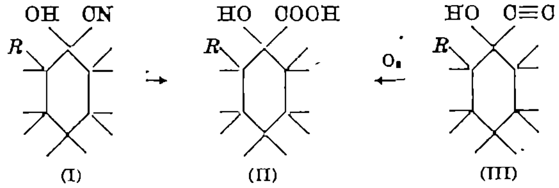
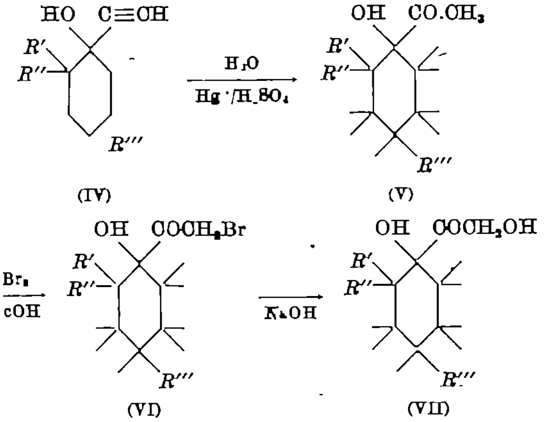
Simple Analogues of Cortisone

IN continuation of previous work from t Department[1], some methyl-substituted analogues 1-hydroxyacetyl*cyclo*hexanol have now been p pared. The previous method employed an α-hydro acid (II, R=H) obtained from its cyanohyd (I, R = H). 2-Methyl*cyclo*hexanone cyanohyd



(I) (II) (III)

uld not be hydrolysed to the corresponding acid I, R=CH$_3$), and although this acid was obtained r the oxidation of the corresponding 2-methyl-1-hynylcyclohexanol (III, R=CH$_3$), the low yields ndered the product unsuitable as a starting material. ence, for further work the method was modified as llows:



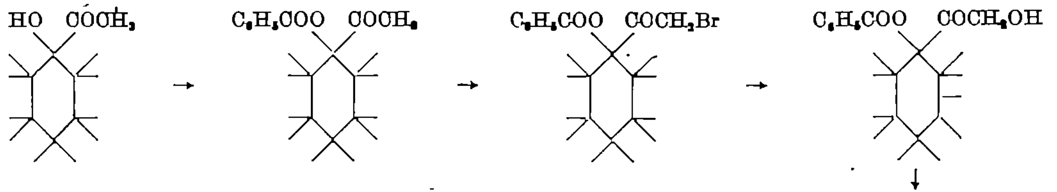
(IV) (V)

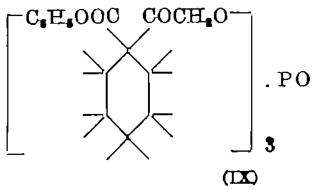
(VI) (VII)

Methylcyclohexanone with sodium acetylide in quid ammonia furnished excellent yields of the s/trans-2-methyl-1-ethynylcyclohexanols[2], which ere roughly separated into the cis- (m.p. 58°,) per cent) and the trans- (b.p. 76°/15 mm., 1·4689, 60 per cent) forms by crystallization. oth forms were hydrated with dilute sulphuric id in the presence of a mercury salt, and the tones so obtained (V, R'=CH$_3$, R''=R'''=H) mpletely purified at this stage through their semirbazones (cis-2-methyl-1-acetylcyclohexanol, m.p. ° ; semicarbazone, m.p. 229–230° ; trans-2-methyl-acetylcyclohexanol, b.p. 92°/10 mm., n_D^{18} 1·4635; micarbazone, m.p. 218–219°). Bromination of the spective ketones yielded cis-2-methyl-1-bromoetylcyclohexanol (VI, R'=CH$_3$; R''=R'''=H, .p. 68–69° ; pyridinium quaternary salt, m.p. 8–190°) and trans-2-methyl-1-bromoacetylcyclo-xanol (b.p. 70°/10^{-4} mm., pyridinium salt, m.p. 2–203°).

The corresponding cis-2-methyl-1-hydroxyacetyl-clohexanol (VII, R'=CH$_3$; R''=R'''=H, m.p. –80°) and the trans-2-methyl-1-hydroxyacetylcyclo-xanol (viscous liquid; semicarbazone, m.p. 199–1°, and thiosemicarbazone, m.p. 210° (dec.)) were tained by hydrolysis of the cis- and trans-bromides.

4-Methylcyclohexanone gave 4-methyl-1-ethynyl-clohexanol (m.p. 20°, evidently a cis- and trans-ixture from which only very small yields of one re form, m.p. 36°, could be separated). On dration, the mixture yielded a ketone (V, R'= ''=H ; R'''=CH$_3$, b.p. 99–100°/10 mm.; semi-rbazone, m.p. 181–182°). Bromination and hydrosis further yielded 4-methyl-1-bromoacetylcyclo-xanol (VI, R'=R''=H ; R'''=CH$_3$, b.p. 125°/0·004 m.) and 4-methyl-1-hydroxyacetylcyclohexanol (VII, R'=R''=H ; R'''=CH$_3$, m.p. 80–81°). Similar reactions on 2 : 2 dimethylcyclohexanone furnished only very small yields of 2 : 2 dimethyl-1-hydroxyacetylcyclohexanol (VII, R'=R''=CH$_3$, R'''=H, m.p. 56°).





(IX)

The present method of introducing the dihydroxyacetone chain into simple compounds allows any desired acylation on the primary and tertiary alcohol functions without resorting to selective acylation, and, as a model, a phosphate of the type (IX) has been prepared (1-acetylcyclohexyl benzoate, b.p. 124·5°/10^{-4} mm., 2 : 4 dinitro-phenylhydrazone, m.p. 200° ; 1-hydroxyacetylcyclohexylbenzoate, m.p. 76° ; phosphate (IX), m.p. 80–81°).

Further details of preparations and biological tests will be published elsewhere.

I am indebted to Prof. N. F. Maclagan for suggesting this work and for advice and encouragement throughout it. I am also indebted to the Empire Rheumatism Council and the Standring Research Fund, Westminster Hospital, for financial assistance.

Paper Chromatography of Phenolic Substances

SEVERAL recent publications have attested to the utility of the technique of paper partition chromatography in the separation and identification of phenolic substances. Bate-Smith[1] described its application to anthocyanins, flavones and other polyphenolic substances using a butanol – acetic acid – water system and ammoniacal silver nitrate as a detecting reagent. Evans, Parr and Evans[2] used butanol – pyridine – aqueous sodium chloride and diazotized sulphanilic acid (Pauly reagent) to separate and detect simple phenols and their derived phenolic acids. Gosta Lindstedt[3], applying the technique to the separation and identification of nine phenolic constituents of pine heartwood extracts, found that best results were obtained with a water-saturated mixture of benzene and ligroin containing traces of methanol. *Bis*-diazotized benzidine was used as the detecting reagent. A phosphomolybdic acid detecting reagent was used by Riley[4] in applying the technique to

Concentration, 14 mgm./c.c., resolved in 3 hr

common phenols in benzene – alcohol – water systems. In studying lignin degradation products, Hossfeld[5] first coupled the phenol mixtures with diazotized sulphanilic acid and then separated the sodium salts of the dyes formed using a methyl ketone – water system.

In work at the Vancouver Forest Products Laboratory on phenolic extracts of conifer heartwood and phenolic compounds related to lignin, the best results have been obtained using carbonic acid solution alone as a developing solvent, and a fine spray of an aqueous mixture of ferric chloride and potassium ferricyanide as detecting reagent. The latter, easily prepared by mixing equal volumes of one per cent ferric chloride and one per cent potassium ferricyanide a few minutes prior to use, gives an instantaneous deep blue spot similar to Turnbull's blue with all phenols thus far tested. A permanent record is secured by washing the paper with dilute hydrochloric acid followed by water.

The formation of a blue spot by ferric chloride and potassium ferricyanide in the presence of phenols may possibly be explained by the formation of a 1 : 1 complex of ferric ion and phenol, as suggested by Broumand and Smith[6], which then gives the ferrous reaction (Turnbull's blue).

The single-phase carbonic acid developing solvent, prepared by bubbling carbon dioxide through distilled water at 21° C. until a pH of 4 2 is reached, gives rapid development (38 cm. in four hours) an good resolution with most phenols.

This simple, but very useful, combination of de veloping solvent and detecting reagent has been use successfully in this laboratory during the past tw years. Results of its application to simple pheno run individually in descending chromatogram o Whatman No. 1 paper at 22° C. are given in th accompanying table. In each case well-define circular spots were detected.

DISTANCE TRAVELLED BY SOME SIMPLE PHENOLS IN FOUR HOU

Substance	Distance (cm.)
α-Naphthol	17 0
β-Naphthol	15·2
Pyrogallol	24 8
Catechol	28 1
Resorcinol	26 0
Phloroglucinol	20·7
Hydroquinone	27·0
Gallic acid	23 6
Vanillin	24·6
Syringaldehyde	20 8

Application to phenols and complex polyphenolic from heartwood extracts is illustrated in the photograph, the chromatograms being, from left to right those of the acetone extract of mountain hemloc (*Tsuga mertensiana*), western hemlock (*Tsuga heter phylla*), western red cedar (*Thuja plicata*), and Dougla fir (*Pseudotsuga taxifolia*), respectively. The usefulne of this technique in family and species identificatio is indicated clearly. The strong spot at R_F 0·26 f the Douglas fir was readily shown by colour tes and comparison with a reference sample to be du to the 3, 3^1, 4^1, 5, 7 pentahydroxy flavanone isolate by Pew[7].

Details of the work on extracts of conifer hear wood will be published elsewhere.

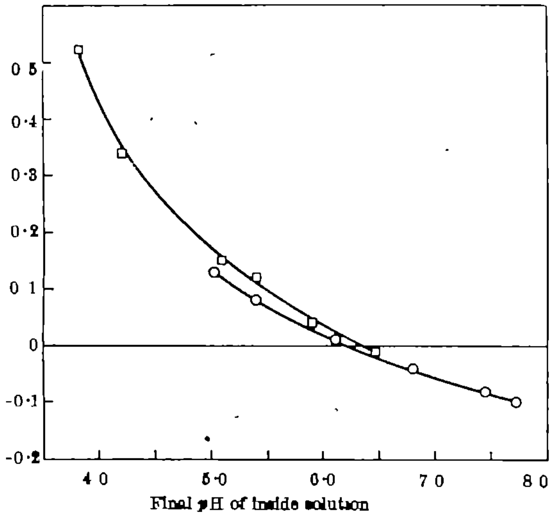
Isoelectric Point of Chymotrypsinogen by a Donnan Equilibrium Method

Kunitz and Northrop[1] found the isoelectric poin of crystalline chymotrypsinogen to be near pH 5 b their method of microcataphoresis[2]. Recentl Anderson and Alberty[3] and Laskowski[4], using electr phoretic mobilities, gave values of pH 9·5 and 9· respectively. As it is now possible to crystalliz chymotrypsinogen salt free from aqueous alcohol it was thought worth while to attempt to determin the isoelectric point of such a preparation by method based on the Donnan equilibrium.



, 8 per cent chymotrypsinogen solution, acetate buffer, 0 004 *M* ; , 9 per cent chymotrypsinogen solution, phosphate buffer, 0 005 *M*

;hymotrypsinogen was prepared by the method of nitz and Northrop[1] and crystallized six times from ıte aqueous alcohol[5]. A 10 per cent solution of protein in water was prepared with the aid of a drops of 1 *N* hydrochloric acid; the final *p*H 3·6. The liquid, which was slightly turbid, was rified by centrifugation at 5° C. Sodium hydroxide, , was added gradually and samples of 4·0 or 4·5 c.c. re withdrawn from time to time and mixed with or 0·5 c.c., respectively, of the appropriate fer of the same *p*H. Lengths of sausage casing, n. diameter (Nu Jax Visking cellulose sausage ing, Visking Corp., Chicago), previously washed l each containing a small glass bead, were filled h this solution to such a length that they fitted ıveniently into a test-tube. This was filled with same buffer suitably diluted, so that the con- trations of buffer salts were identical on both es of the membrane. The initial *p*H of the inner l the outer solutions differed by less than 0·02 *p*H ts. The test-tube was then closed with a rubber pper, leaving a small air-bubble to provide stirring the outer solution. Several of these tubes were tened along the radii of a slowly revolving vertical k and were thus kept stirred for 24 hr. at 5° C. unopened tubes were allowed to warm to room nperature for 20 min. The *p*H of the outer solution s measured first, followed immediately by measurent of the inner solution.

'he graph of the final *p*H of the inner solution inst the difference in *p*H between the solutions the two sides of the membrane is reproduced ewith; the point of zero difference, which is the electric point, is seen to lie at *p*H 6·3. It is interest- to note that the monovalent acetate buffer and polyvalent phosphate gave almost identical values the isoelectric point. A similar experiment with onal–acetate buffer, 0·004 *M*, gave less clear ults, but indicated an isoelectric point between 6 and 7.

This method has the advantage that it can be ried out very simply with a minimum of equipnt, provided that the protein is readily available l is stable under the conditions employed. It none of the disadvantages of the other methods rently in use, except the possibility of combination between protein and the buffer salts; this can, however, be investigated by using diverse types of buffers.

The microcataphoresis[4] of collodion particles coated with chymotrypsinogen gave indications that the protein concentration affects the value of the isoelectric point, higher values being obtained in stronger concentrations. For example, the above preparation of chymotrypsinogen gave a value of *p*H 7·2–7·4 when the concentrations were as high as 0·4–0·8 per cent, $\mu = 0 \cdot 0058$. The state of purity and the previous history of the protein appear also to have an important influence on the result.

I am indebted to Dr. M. Kunitz for his guidance and help and for permission to work in his laboratory. The experiments were carried out during the tenure of a Rockefeller Foundation Fellowship.

Basic Chromosome Numbers in the Genus *Cerastium*

AN investigation of mitotic chromosomes of *Cerastium semidecandrum* L. (British material) has revealed that, of the 36 metaphase chromosomes, four are nucleolar-organizing chromosomes. These each have a satellite. The nucleoli fuse early in telophase since the resting nuclei have only one, two or, more rarely, three nucleoli, though once a cell with four nucleoli was seen. It would thus seem that these $2n = 36$ plants are tetraploid, although no plant with $2n = 18$ has, as yet, been reported, and that nine is finally established as the basic number. From chromosome counts most species in the genus have nine as the basic number; however, there is a group of species, all annuals, which have the chromosome number $2n = 38$. In these plants the nucleolar-organizing chromosomes cannot be distinguished in somatic tissues; but in the pollen-mother cells there are two nucleolar-organizing chromosomes clearly visible during prophase. These two chromosomes each have a distinct deeply staining region in contact with the nucleolus, such as McClintock[1] described in *Zea mays*. It would thus seem that in this section of the genus the plants are truly diploid with 19 as the basic number. A list of species for which chromosome counts are available is given below, with the species grouped according to their basic numbers. Unless otherwise stated the material is continental; undated counts are published here for the first time.

From these lists it is apparent that the majority of the species in the section Orthodon have the basic number 9, while those in the section Strephodon have the basic number 19. A few species, for example, *C. dichotomum*, normally placed in the section Orthodon, would appear from cytological evidence to have a closer relationship with the

C. *maximum*	38	Brett (Alaska)
C. *perfoliatum* L.	38	Brett, 1950; Sollner, 1950

Strephodon species *C. perfoliatum*. It would also appear, as Söllner[2] has already suggested, that the Dichodon species *C. anomalum* is related to *C. perfoliatum* and, in my opinion, to *C. dichotomum* also. Further investigation it is hoped will result in a more natural classification than that formulated by Seringe and published originally by de Candolle[3].

Other counts in these lists call for comment. Three species, *C. cerastoides*, *C. arvense* and *C. tomentosum*, appear to have both basic numbers. The morphological and geographical evidence would suggest that they belong to the $x = 9$ group and possibly, therefore, the 38 and 40 chromosome members are aneuploids, $4x + 2$ and $4x + 4$.

The species *C. holosteoides* (*C. vulgatum*) is peculiar in that its chromosome number is not constant even for the offspring of the same plant after selfing. This species is a very high polyploid, probably 16-ploid, and it would seem that, at this degree of ploidy, loss or gain of a few chromosomes at meiosis has little if any effect upon the viability and fertility of the seed. The range of chromosome numbers given as 136–152 is probably wider than this, as approximate counts have been made which indicated even lower and higher numbers. Many multivalents are found at first metaphase, and it is thought that different numbers pass to the poles at first anaphase. Lagging chromosomes, though found, are by no means the
rule, and usually all the chromosomes are includ
in one of the four nuclei at the end of meiosis.

The question of the origin of these two bas
numbers remains. It is possible that their origi
are quite distinct; but, alternatively, it could
that as a result of hybridization the plants wi
38 chromosomes have the activity of all but two
their nucleolar-organizing chromosomes suppresse
the situation being similar to that discovered
Nevashin[4] in *Crepis*.

OLIVE E. BRETT

Colonization of Plant Debris by *Coprinus* Species in Soils

ISOLATION of members of the group Basidiomycete
as compared with other soil fungi, directly from s
by either the soil dilution plate[1] or the root buri
technique[2] has met with little success, though bett
results have been obtained by the soil plate techniqu
Hitherto, studies on their distribution were most
confined to the recording of fructifications (whi
may be of seasonal occurrence) in Nature[4]. Howeve
in the course of investigations in this laboratory
survival of *Macrophomina phaseoli* by the root buri
technique in Madras garden soil amended wi
ammonia at different concentrations (2, 5 and 10 p
cent), it was observed that a Basidiomycete regular
colonized and produced fructifications on pieces
cotton root when plated on agar media (potat
dextrose and Horne and Mitters's media). The incub
tion period needed in the soil for this colonizati
was only two weeks. The control pieces of root buried
untreated soil failed to yield the fungus. This wo
was extended to cotton-growing soils, namel
Coimbatore, Udamalpet and Kovilpatti soils (Madr
State). In all cases similar fructifications we
observed only in the soils treated with ammonia. T
Basidiomycete was also found to colonize and produ
its fructifications on pieces of root soaked in 50 p
cent ammonia solution for one hour and incubat
for one week in the above-mentioned soils. T
fungus has been identified as a species of *Coprin*

I am indebted to the Director, Royal Bota
Gardens, Kew, for the identification of the Basid
mycete, and to Prof. T. S. Sadasivan, for help a
guidance during this investigation. My thanks
due to the Government of India for the award o
Junior Research Scholarship.

Filarial Infections in Mosquitoes

Mosquitoes which on dissection show infective ırial forms are often regarded as vectors of human ıriasis in a particular area where mosquito coltions are made. As mosquitoes of the same species ıy also play the part of vectors of animal filarial ections, findings in any given area have to be erpreted carefully. A short account of conditions rtaining in a small village in Sakhigopal, Orissa State, dia, where *Wuchereria bancrofti* is the known cause filarial infection in man, is given below.

Of 3,307 *Culex fatigans* and 1,928 *Mansonioides nulifera* dissected locally, 55 of the former and 41 of ə latter were found with infective larval forms in ə head/proboscis. In addition, some *M. annulifera* owed microfilariæ or their developing forms in the alphigian tubes. In view of the fact that *M. nulifera* are not suitable for transmission of *W. ncrofti* and that *Wuchereria* develop in thoracic ıscles[1], the possibility of filariæ of other origins ısting in the same area was explored. Infective rvæ dissected out from *C. fatigans* were longer than ose noted in *M. annulifera*. The former had more an one caudal protuberance, indicating that they ɪre probably *Wuchereria*.

Precipitin tests of blood-meals of mosquitoes ɪre carried out to determine the sources of blood. ıey showed a higher predilection of *C. fatigans* for ıman blood than *M. annulifera*, which fed mainly domestic animals and birds.

Four out of forty dogs examined were found sitive for microfilariæ, morphologically similar to *rofilaria repens*.

Separate batches of clean *C. fatigans* and *M. nulifera* were allowed to feed on dogs showing *repens* infection, and on human cases with *W. ncrofti*. Results showed that a high percentage *M. annulifera* became infective with *D. repens* but ɪre refractory to infections with *W. bancrofti*. On e other hand, *C. fatigans* showed high susceptibility infections with *W. bancrofti* and definite refractoriss to development of *D. repens* in them. These ints serve to bring out the importance of correct sis of infective forms of filarial infections in uitoes.

annulifera has been incriminated as a vector *D. repens*.

bnormal Leaves of *Cycas revoluta* Thunb.

During the course of an investigation on the position of xylem in the rachises of cycads, I me across a peculiar abnormality in *Cycas revoluta* ıunb. In some female specimens, several leaves essed a subsidiary rachis which bore subsidiary nnæ in a spiral fashion. This was noted in several ccessive whorls.

Each subsidiary rachis appeared to originate by a nspicuous fold of the main rachis. It was filled ainly by parenchyma. The sides were composed of a nified epidermis and one to two layers of thickılled hypodermal cells. The epidermis was heavily tinized, but was interrupted by sunken stomata of the normal type. There was a layer of palisade tissue immediately below the epidermis at several places; but its disposition was not uniform (Fig. 1). The vascular bundle was mesarch and included in the inner margin of the rachis. The subsidiary rachis was observed only in the distal half of the leaf, and did not exceed 7 cm. in length.

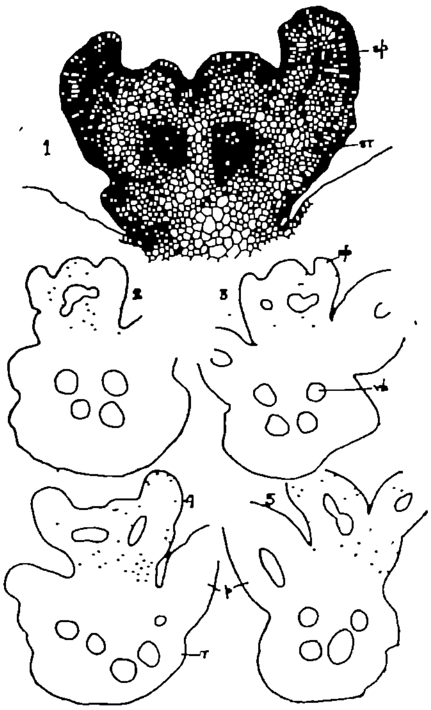

Fig. 1. A part of the transverse section of rachis showing the vascular bundle of subsidiary rachis in division. (× 44)

Figs. 2–5. Changes in the outline of the rachis during the emergence of subsidiary pinnæ. (× 12)

p, Normal pinnæ; *r*, principal rachis; *sp*, subsidiary pinnæ; *sr*, subsidiary rachis; *vb*, vascular bundles

The subsidiary leaflets were formed by lateral elongation of the rachis and the constriction of the newly formed parts. Each leaflet had the normal structure; but the vascular tissue was very scanty. The transfusion tissue was formed by gradual thickening and elongation, from a mass of loose cells in the rachis which appeared while the leaflet primordium was yet being formed. The vascular bundle of the subsidiary pinna was diffuse at the origin but gradually assumed concentric and then mesarch structure[1].

In an examination of the successive stages of the origin of the subsidiary pinnæ (Figs. 2–5), it was found that the subsidiary rachis lost its identity as the pinnæ matured. The normal structure of the principal rachis was regained by a gradual suppression of the subsidiary rachis and disappearance of its vascular bundle.

Such a feature is unknown in other cycads and has not been reported hitherto as a normal occurrence in *Cycas*.

I am grateful to Prof. Shri Ranjan for his encouragement, and to Mr. G. P. Agarwal and Mr. B. B. S. Raizada for help in the preparation of sections.

Ramesh Kumar Srivastava

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Biochemist (fully qualified with training and experience in hospital laboratories)—The Superintendent, Hope Hospital, Salford 6 (August 16)

Assistant in Mathematics—The Secretary, The University, Edinburgh (August 21).

Assistant in the Department of Geography—The Secretary, The University, Edinburgh (August 23).

Assistant Professor in the Physics and Electrical Engineering Department—The Director of Studies, Royal Naval College, Greenwich, London, S.E.10 (August 23).

Chemist (with honours degree in chemistry or A.R.I.C. and post-graduate analytical and research experience) at the Central Laboratory at County Hall—The Medical Officer of Health (PH/D.1), London County Council, County Hall, London, S.E.1 (August 23).

Lecturer in Physiology and Pharmacology in the School of Pharmacy—The Principal, Technical College, Dundee (August 23).

Research Demonstrator in Zoology—The Registrar, The University, Sheffield (August 23).

Senior Lecturer in Metallurgy (with a wide knowledge of the metallurgical industry, with detailed knowledge of at least one branch of importance locally) in the Department of Applied Science, Wolverhampton and Staffordshire Technical College—The Clerk to the Joint Educational Committee, Education Offices, North Street, Wolverhampton (August 23).

Head of the Department of Science (comprising chemistry, physics, biology, mathematics)—The Principal, College for Further Education, Wellington Road South, Stockport (August 27).

Plant Physiologist (with a good honours degree in botany, with special reference to plant physiology, and preferably some post-graduate experience) under the Colonial Development Welfare Cocoa Research Scheme, Trinidad—The Secretary, Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2 (August 29).

Soil Chemists and Soil Surveyors (with a good honours degree in chemistry (or geology for soil surveyors) and, preferably, some postgraduate experience) under Colonial Development and Welfare Research Schemes for Soils and for Cocoa, Trinidad—The Secretary, Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2 (August 29).

Assistant in the Department of Animal Husbandry and Preventive Medicine in the University Veterinary School—The Assistant Secretary of University Court, The University, Glasgow (August 30).

Assistant Lecturer in Geology (with special qualifications in petrology)—The Registrar, The University, Sheffield (August 30).

Assistant Lecturer or **Lecturer in the Department of Electric Power Engineering**—The Registrar, The University, Liverpool (August 30).

Operational Research Posts in the Field Investigation Group of the Directorate of Scientific Control—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/511 (August 30).

Research Officer (with an honours degree in zoology or agricultural science, or equivalent, with first-hand experience in the conduct of field ecological investigations on either mammals or birds) **in the Wildlife Survey Section** of the Commonwealth Scientific and Industrial Research Organization, either at headquarters at Canberra or at the field station at Albury, N.S.W., to undertake field ecological studies of mammals and birds of economic importance—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3925 (August 30).

Teacher of Chemistry, and a **Teacher of Physics**, to undertake part-time teaching of intermediate standard—The Registrar, Nottingham and District Technical College, Shakespeare Street, Nottingham (August 31).

Examiners in Chemistry and Physics, Biology (Botany and Zoology), **Physiology** (including Biochemistry) **of the Domesticated Animals, Histology and Embryology, Animal Management, Anatomy of the Domesticated Animals, Pharmacology, Materia Medica and Pharmacy, Veterinary Hygiene, Dietetics and Animal Husbandry, Veterinary Pathology, Veterinary Parasitology, Veterinary Medicine, Veterinary Surgery**—The Registrar, Royal College of Veterinary Surgeons, 9–10 Red Lion Square, London, W.C.1 (September 1).

Principal Scientific Officer (with a first- or second-class honours degree in engineering, mathematics or physics, or equivalent qualifications) at the Mechanical Engineering Research Laboratory, East Kilbride, Glasgow, to lead a small team on work initially concerned mainly with the general field of stress analysis, both analytical and experimental, and later including vibration and photo-elasticity—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4159/52 (September 4).

Research Officer—Physical Chemist (with University honours degree in physics or chemistry, or equivalent qualification) **in the Division of Food Preservation and Transport** at the University of Sydney, for studies in the physical chemistry of proteins—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting No. 3932 (September 6).

Lecturer in Physics at University College, Dundee—The Secretary, The University, St. Andrews (September 8).

University Graduate (with first- or second-class honours in botany, with qualifications in mycology) **in the Microbiological Section** of the Department of Soil Organic Matter—The Secretary, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (September 12).

Experimental Officers at the Atomic Energy Research Establishment, Harwell, for mechanical engineering experimental and developmental work—The Ministry of Labour and National Service, Technical and Scientific Register (K), Almack House, 26 King Street, London, S.W.1, quoting A.209/52A (September 13).

Lecturer or **Assistant Lecturer in Biochemistry**—The Registrar, The University, Sheffield (September 13).

University Lecturer in Philosophy of Science—Mr. L. Harvey, The Old Schools, Cambridge (Septe[illegible]r 14)

Lecturer, Grade II (graduate in pure [illegible]pplied science or equivalent, with bacteriology as a ma[illegible]bject) **in Patholog** at the University of Queensland—Th[illegible]retary, Association Universities of the British Commonwea[illegible], Gordon Square, Londo W.C.1 (September 15).

Principal Scientific Officer and a **Senior Scientific Offic** at a Ministry of Supply Experimental Flying Establishment ne Salisbury: **Principal Scientific Officer** (engineer or physic with mathematical ability, or an applied mathematician with practical outlook) to cont[illegible] staff engaged mainly in research a development of flight testing methods and techniques: **Senio** **Scientific Officer** (engineer, physicist or applied mathematici with some experience in aeronautical research) to undertake theoretic and analytical work on the development of helicopter testing tec niques and general research on helicopter flight problems—The Civ Service Commission, Scientific Branch, Trinidad House, Old Burlingt Street, London, W.1, quoting S.4160/52 (September 25).

Senior Lecturer in General Chemistry at the University Melbourne—The Secretary, Association of Universities of the Britis Commonwealth, 5 Gordon Square, London, W.C.1 (October 31).

Assistant (Grade A or B according to qualifications and experienc **in the Mathematics Department**—The Principal, Derby Technic College, Normanton Road, Derby.

Assistant Lecturer in Natural Philosophy—The Secretar Royal Technical College, Glasgow.

Assistant Lecturer, Grade B (with a University degree) to tea botany and zoology at intermediate standard and physiology an anatomy for ophthalmic optics—The Principal, West Ham Colle of Technology, Romford Road, London, E.15.

Biochemist (with an appropriate science degree or the A.R.I.C **in the Department of Pathology**—The Group Secretary, Roy Infirmary, Bolton.

Chemists (Principal Scientific Officer or Senior Scientific Offic grade) at Ministry of Supply London headquarters: duties includ the initiation and progressing of research and development on textil for Service purposes—The Ministry of Labour and National Servic Technical and Scientific Register (K), Almack House, 26 King Stree London, S.W.1, quoting F.533/52A.

Chemists and **Chemical Engineers** (Senior Scientific Officer grad at Ministry of Supply London headquarters for work concerned wit guided weapons: (*a*) to sponsor the development and exploitation new materials, structures, and technical development for engineerin processes (Ref. F.519/52A); (*b*) to assess the relative performance different propellants and warheads under service conditions and t progress and assist development work on them (Ref. F.520/52A)—The Ministry of Labour and National Service, Technical and Scientifi Register (K), Almack House, 26 King Street, London, S.W.1, quotin the appropriate Ref. No.

Electrical Engineers and **Physicists** (with a first- or second class honours degree or equivalent in electrical engineering or physic (Scientific Officer grade) at the Royal Aircraft Establishment, Farn borough—The Ministry of Labour and National Service, Technic and Scientific Register (K), Almack House, 26 King Street, Londo S.W.1, quoting D.302/52A.

Junior Analyst (with good experience in metallurgical analytic work)—The Secretary, British Welding Research Association, 29 Par Crescent, London, W.1.

Mycologist (with rank of Assistant Professor) **in the Botan Department**—The Chairman, Department of Botany, McGill Univer sity, Montreal 2, Canada (apply by airmail).

Research Engineer (B.Sc. or equivalent, and some engineerin workshop and drawing office experience essential) for design and testin of experimental equipment—The Assistant Secretary (Ref. A.19, British Coal Utilisation Research Association, Randalls Road, L[illegible]therhead, Surrey.

Scientific Officer (with a first- or second-class honours deg[illegible] chemistry, physics or chemical engineering) at the Food Investiga[illegible] new Humber Laboratory, Hull, to carry out research in physica[illegible] physico-chemical problems on the preservation of fish by smo[illegible] drying, etc.—The Ministry of Labour and National Service, Tech[illegible] and Scientific Register (K), Almack House, 26 King Street, Lon[illegible] S.W.1, quoting F.303/52A.

Senior Physicist (with experience in medical physics) for Radi therapy Service of the Southampton area—The Secretary, Southampto Group Hospital Management Committee, Bullar Street, Southampton.

Senior Services Engineer in the Division of Atomic Energ (Production), Capenhurst, Chester, to be directly responsible to th Chief Factory Engineer for all the engineering services (electrical, civil mechanical) and the associated workshops required in the operatio and maintenance of a large chemical engineering factory—Th Ministry of Supply, Division of Atomic Energy (Production), Risley Warrington, Lancs, quoting Ref. 358.

JOINT CONSULTATION IN MANAGEMENT

WHEN the Committee on Industrial Productivity, appointed in December 1947, formed its Panel on the Human Factors affecting Industrial Productivity, under the chairmanship of Sir George Schuster, one of the first subjects to which the Panel turned its attention was current managerial practice. The soundness of this decision has been confirmed by the experience and reports of the productivity teams which have since been sent by the Anglo-American Council on Productivity to study American practice in various industries. Two of the outstanding lessons to be learned from the experience of these teams are the extent to which efficient management sets the pace of productivity and the importance of dealing with those engaged in industry as human beings whether at the level of the operative, the foreman, the technologist or the manager.

Two extensive surveys in this field were planned by the Panel and were undertaken under its sponsorship by the National Institute of Industrial Psychology : one was into the status, selection and training of foremen and the second was into methods of joint consultation. Both inquiries were designed to present a picture of current practice in the whole range of industry and to relate the nature and the effectiveness of the methods in use to the size, location, internal structure and history of the firms approached. A report on the first project has already been published. That on the second, which occupied three years, during which 189 factories were visited and information received from many others, has now appeared*, appropriately enough when the Acton Society Trust has issued a corresponding but slighter study of joint consultation in the nationalized industries, which were excluded from the inquiry initiated by the Panel on Human Factors†.

The report seeks to elucidate the factors associated with successful joint consultation, and after defining the scope of the inquiry, the purposes of joint consultation and the criteria of success, analyses, in successive sections, psychological conditions and their effect, the bearing of technical and economic factors, the organization and finally the achievements of joint consultation. In the last two chapters of the book joint consultation is discussed first from the point of view of the worker in broad terms and then from that of the manager, both as leader and as employer. There is also a foreword by Sir George Schuster.

It is by no means clear to whom the book is addressed, and probably something much more concise would have been surer of reaching the average factory executive, trade union official or works council representative, particularly if the details were made accessible to those sufficiently interested. Much of the material or evidence here presented is indeed of general interest ; but the task of exposition seems scarcely to have been attempted and is perhaps the more important because the conclusions drawn from this study are so slender. There can, in fact, be no one best form of structure and procedure for joint consultation. An appropriate system for a particular company must take into account the circumstances of that company—the material conditions, its organization, and the relationships and prevailing attitudes of the people at all levels within it. Those concerned with setting up a new organization or system will undoubtedly find that this report will amply repay a careful study.

---

* Joint Consultation in British Industry. A Report of an Inquiry undertaken by the National Institute of Industrial Psychology sponsored by the Human Factors Panel of the Committee on Industrial Productivity. Pp. 276. (London : Staples Press, Ltd., 1952.) 21s. net.

† The Framework of Joint Consultation. By J. H. Smith and Miss R. J. Carey. (Nationalized Industry Series, 10.) Pp. iii+35. (Claygate : Acton Society Trust, 1952.) 2s.

"Any system of joint consultation, however, cannot long remain static and effective: it must develop to meet the changing needs of the organization or its usefulness will decline and it will gradually decay." To preserve vitality involves a task of mutual understanding and of education on both sides, and it is here that something more is required in the way of exposition or interpretation than we are given here. As a technique of management the scope of joint consultation is limited, and unless those limitations are clearly and generally understood there is the danger that unfounded expectations may lead to disappointment and further distrust instead of to confidence and harmony.

As a philosophy of management, joint consultation has wider possibilities; but here again there is much educational work to be done before it is fully understood and accepted with all its implications as the development of a democratic principle. Adoption of the consultative relationship as the basis for day-to day conduct of the affairs of an organization is likely to foster the growth of understanding and realization of a common purpose between people whose interests may appear to them to be opposed; but there are examples enough given in this book to show how much has yet to be done to remove misconceptions and misunderstandings. Sir George Schuster, in his foreword, indeed suggests that while some important firms are making great advances, British industry as a whole is still only tinkering with the subject. Joint consultative methods, he urges, are a means to an end—the making of each industrial unit a harmonious, live, co-operating community, working together with a sense of common purpose which is understood and accepted by all its members. That ultimate aim is kept in view in this book, and if it does not go quite so far as is desirable in the task of exposition and interpretation, at least it provides a large amount of material from actual experience on such matters as the form of committees, the methods of selecting representatives, the difficulties of 'reporting back' the problems of relations with the trade unions and the like with which others could complete that task.

The Acton Society Trust paper brings out quite as well the need for a clear understanding of what is meant by joint consultation and advisory functions; but the position in the nationalized industries as given in this pamphlet differs considerably from that given by the study initiated by Sir George Schuster's Panel. All the industries nationalized since the War have been placed under a statutory obligation to set up machinery for joint consultation as well as for the negotiation of wages and conditions for employees. Primarily the Acton Society Trust sought to compare the varying organization established in the different industries, to inquire as to its effectiveness in practice and to consider the extent to which the size of the industries had created special problems for the working of consultation. In practice, the inquiry could not be limited to structure because defects in working arose from many varied causes.

In spite, however, of the differences, this study of nationalized industry corroborates much of the evidence given in the fuller inquiry of the Panel on Human Factors affecting Industrial Productivity. Indeed, the very factors which, in the nationalized industries, have been responsible for the difficulties in the way of joint consultation that have hindered its development on the lines expected and have even led to its impairing instead of improving relations, arise out of neglect of the conditions for successful joint consultation stressed by the inquiry into industry in general. The unions' insistence on uniformity of treatment in the nationalized industries and their desire to apply decisions over the largest possible area, the apprehensions of management, and the over-riding tendency of management and the trade unions to treat consultation as a method of exerting power, rather than as a method of exchanging views (with all the complications and untoward consequences of these attitudes and tendencies), are at bottom due to a complete misconception of the nature of joint consultation which the contrast drawn in these industries between joint consultation and negotiation tends to accentuate.

Until that misconception is removed, the realities of the situation will not be faced and there is little hope of real progress. The report prepared by the Panel on Human Factors is a real contribution to the task of education required, and, although the data it presents are drawn from outside the nationalized industries, they are as relevant to the problems of those industries as to the problems of industry elsewhere. It is to be hoped that the report will be carefully studied by all sections of nationalized industry, and that its findings and evidence will be further interpreted and expounded in a form likely to reach those who may never read the present report.

The Acton Society Trust does not present its study of the existing structure in the nationalized industries without some positive suggestions. Five general conditions are postulated for the organization of successful joint consultation: the structure must be comprehensible to those who use it; it must be laid down in an agreement between management and the unions; it should be subject to review and amendment; it should be developed in response to local demand; and it should include adequate arrangements for reporting back the proceedings of committees to those represented. Beyond this it suggests that the structure should also be related in some way to the manner in which employees are organized into working groups. The fourth and fifth conditions are those where the position is least satisfactory, and like the itative sixth condition they demand much more ention and examination in the light of a concep- n of consultation as a continuous relationship ween groups of people which requires expression appropriate forms.

In this study, however, the main emphasis is on task of education. The most serious omission in present arrangements in the nationalized indus- es, it is urged, is the general failure to provide any chinery for passing information about the work of committees to the men they represent. As in the dy initiated for the Committee on Industrial oductivity, emphasis is laid on the need for skilled dership in the development of harmoniously work- group or committee; but the main challenge of th these inquiries is to the task of education. esh constructive thinking about joint consultation th as a technique and as a philosophy of manage- nt is needed; but the most urgent need is to secure widespread and clear understanding of what joint nsultation really is, its limitations and its possi- ities. For that task the report in particular supplies ich useful material, but the Acton Society Trust per is equally designed to stimulate the interpreta- n and exposition on which must be based an ucational campaign as it desiderates.

BOTANY FOR THE DEGREE STUDENT

xtbook of Theoretical Botany

Dr. R. C. McLean and Dr. W. R. Ivimey-Cook. l. 1. Pp. xv+1069. (London, New York and ronto: Longmans, Green and Co., Ltd., 1951.) s. net.

"THE attempt to write a textbook of Botany is an audacity which admits of no excuse but suc- ss." Few would disagree with this prefatory mark in the first volume of the new text-book of eoretical botany; all will admire the audacity, even excuses are not sought, and may, indeed, ask if it not audacity for a reviewer to attempt to criticize er so wide a field.

The authors have made no attempt at specialist eatment, but have tried to bridge the gap between e specialist books and those designed for first-year udy. Realizing that the complete work will be both stly and bulky, they have sought to arrange their xt so that it will serve for a beginner as well as for more mature general botanical student. The aim, oreover, is to place factual material in the hands the student and thus to free his teachers from the ed to use their precious lecture time for presenting aterial of this sort.

It is on this basis, therefore, that the first volume the new text-book must be judged, and the first sentials are that it shall be accurate, and lucid ough not to mislead. Mistakes could scarcely be oided in a work of this magnitude; but fundamental rors, or vague and misleading statements, are not be expected. It is on this count that the work falls ort of perfection. A few examples may be given, ough others might have been selected: p. 30, in e metaphase of meiosis, "the homologous pairs of romosomes unite, then come on to the equatorial plane and separate, so that one whole chromosome of each pair goes to one pole and one to the other"; p. 31, reference is made to the heterotypic and homotypic divisions; and p. 32, Fig. 16 illustrates "formation of chiasmata in unsplit homologous chromosomes".

In an account of the algæ, which, the algologist might perhaps complain, have been afforded less generous treatment than the fungi, matters are little better: the definition of heterogamy on p. 51 is difficult to harmonize with that on p. 59; and on p. 104 the life-cycle diagram of *Cladophora* includes reference to an antheridium and an oogonium and to an antherozoid and an oosphere, while in that of *Dictyota* (p. 127) the implication that oogonia and antheridia occur on the same plant is, at best, misleading.

Equally unhappy are statements in other sections of the book: Fig. 697 is not likely to convince even the less sceptical students that there is much difference in the pitting of the araucarian tracheid and that of other conifers; the terms alburnum and duramen (p. 897) and autumn wood (p. 903) are surely a little out of date; does hæmatoxylin oxidize to logwood (p. 898)?; the account of tension and compression wood (pp. 904–7), if correct, is not remarkable for its lucidity, while the statement that, in trees grown in an equatorial climate, growth (of the wood) is continuous, is not as cautious as one might wish.

The book contains more than a thousand illustrations, and the authors are to be congratulated on the large number which are new. Many are from original photographs; but with some, and not a few, the reader may well not feel inclined to agree that the "naturalistic quality of photographs needs no emphasis": if examples are desired, reference may be made to Fig. 30, of *Chlamydomonas*, Fig. 88 of a *Gunnera* rhizome with *Nostoc* colonies, Fig. 269 of yeast, while it is doubtful if Fig. 857 would be recognized as collenchyma. The plain fact would seem to be that a good drawing is often greatly to be preferred to a photograph, and some of these illustrations appear to furnish ample confirmation of this contention.

FRANK W. JANE

ENZYMES

The Enzymes

Chemistry and Mechanism of Action. Edited by James B. Sumner and Karl Myrbäck. Vol. 1, Part 1; pp. xvii+724; 13.50 dollars. Vol. 1, Part 2; pp. x+725–1361; 12.80 dollars. Vol. 2, Part 1; pp. xi+790; 14.80 dollars. Vol. 2, Part 2; pp. xi+791–1440; 14 dollars. (New York: Academic Press, Inc., 1950–52.)

THE publishers of these four books, two parts to each of two volumes, have printed at the front and top of the jacket the words "A new encyclopædic work". The stunned reviewer might be forgiven for doing no more than feebly murmur "Agreed, agreed"; but to do so might suggest discourtesy to editors, authors, publishers and potential readers. Despite the obvious fact, therefore, that such a treatise can scarcely more easily be reviewed than it could have been written by one person, an attempt should at least be made to indicate the scope of the work, of which the first part was published no less recently than December 1950. During the subsequent eighteen months the three remaining parts have brought the total number of pages to 2801. The two parts of each volume have been paginated continuously but separately: at the end of Vol. 1 (1362 pp.) are an author index (49 pp.) and subject index (46 pp.); the corresponding figures for Vol. 2 (1440 pp.) are 53 and 49 pp. At the foot of each page of index to Vol. 2 is repeated a statement to show on which pages Part 1 of the volume ends and Part 2 begins; unfortunately, no such convenient reminders appear in the index to Vol. 1.

In Great Britain, where divers systems of giving references pertain, scientific readers are developing an almost pathological interest in the method adopted by particular authors or editors. For their information it should be stated that in these four volumes references are indicated by serial superscript numbers, the full bibliographical details appearing at the bottom of the page of first mention. This has made necessary a procedure that is a little puzzling at first, for we find as a note to the author index of Vol. 1 the words "The numbers in parentheses are footnotes". This is explained by clearer and more extensive phraseology in a footnote to the corresponding index of Vol. 2, where it is made apparent to the probably baffled users of Vol. 1 that the bracketed numbers are, in fact, the serial reference numbers to papers mentioned on a particular page but given full descriptions on an earlier page. In this matter also, therefore, the editors have in Vol. 2 made good a defect of Vol. 1. With the textual superscripts, the description at the bottom of the individual pages and the two complete author indexes, details of a paper by a particular author can be found at a reasonable speed and one that on the average varies inversely as the author's fecundity. The same paper may, naturally, appear under two separate reference numbers in two chapters, but not in the same one.

There are altogether seventy-eight different names given in the lists of authors at the beginning of the four parts. Their national distribution is, in itself, of some interest: United States, 48; Great Britain, 9; Sweden, 8; Finland, 3; Germany, France and Denmark, 2 each; Turkey, Australia, Switzerland and Belgium, 1 each. There happen also to be just seventy-eight chapters to the combined two volumes; but this is pure coincidence, for sixty-three chapters have single names at their heads (in several instances the same names appear over at least two chapters), eleven are the result of dual authorship, and four come from a treble collaboration.

At the risk of appearing invidious by selecting particular authors for individual mention, it seems nevertheless legitimate to record those of the British contributors, Dr. E. P. Abraham (penicillinase), Dr. N. J. Berridge (milk coagulation), Prof. F. J. W. Roughton and Dr. A. M. Clark (carbonic anhydrase), Prof. Frank Dickens (anaerobic glycolysis, respiration, and the Pasteur effect), Dr. S. R. Elsden (bacterial fermentation), Prof. H. A. Krebs (oxidation of amino-acids; urea synthesis), Prof. J. R. Marrack (enzymes and immunology), Dr. E. A. Moelwyn-Hughes (physical chemistry and chemical kinetics of enzymes). These authors and their subjects are, incidentally, random samples of both, for the net of the editors has been cast so wide as to make nationality a variable independent of subject—in both senses of the word. They therefore convey a fair notion of the breadth and depth of the editors' plans and achievements; this is substantiated when we find such further names as those of Holman and Bergström (lipoxidase or unsaturated-fat oxidase Bernheim (enzymes in detoxication), Philip Cohe (transaminases; enzymatic synthesis of glutamine peptide bond synthesis), Fromageot (sulphatases desulphinase; desulphhydrases; oxidation of organ sulphur), Greenberg (arginase), R. S. Harris (th aminase), Kalckar (dephosphorylation of adenosir polyphosphates), Massart (enzyme inhibition), th late Otto Meyerhof (enolase; aldolase and isomerase Michaelis (theory of oxidation-reduction), Ocho (fumarase and aconitase; enzymatic mechanisms carbon dioxide fixation), Seegers (blood coagulation Theorell (flavin-containing enzymes; the iro containing enzymes, catalases and peroxidase "hydroperoxidases"), Umbreit (hydrogenase an hydrogenylase), Virtanen with J. Erkama (aspartas and N. Rantanen (nitrogen assimilation).

This additional, almost random, selection chapters, written by authors whose original contrib tions to the subject are known all over the world, give a further idea of the ground the editors set out t cover. They themselves contribute a foreword an the opening chapter, simply entitled "Introduction" in it they cover such various topics as definition terminology, classification, history, the chemical an general properties of enzymes and the determinatio of their activity. The anatomy of this chapte naturally differs from that of the others; but thes also show no common pattern, each author or grou of authors having—wisely, I think—been left t devise the most appropriate subdivision of subjec matter.

To the topics already enumerated above, others particular interest may be mentioned, namely, enzym specificity (Helferich), acetylcholine hydrolysis an synthesis and choline esterases and acetylas (Augustinsson), the α-D- and the β-glucosidase (Gottschalk and Veibel, respectively), pectic enzyme (Kertesz), proteolytic enzymes (E. L. Smith), pho phorylases (Hassid, Dondoroff and Barker), th fundamental physical chemistry of phosphate bond (Kaplan), the cytochromes (K.-G. Paul), luminescenc phenomena (Harvey), photosynthesis (Loomis), tumo enzymology (Greenstein and Meister) and—the las chapter of Vol. 2, Part 2—enzyme technolog (Langlykke, Smythe and Perlman). Here also w find evidence of wide scope and authoritativ treatment.

The most casual dipping into these pages, edited b Dr. J. B. Sumner (of Cornell University) and Dr. Ka Myrbäck (of the University of Stockholm), indicat what more intensive reading confirms—the extr ordinary thoroughness with which the field named i the book's sub-title has been surveyed. Despite th intensity of investigation still maintained in th field, showing no signs of abatement and involvi the publication of much new knowledge since eve the latest in date of the book's content went to pres this work must remain for many years what certainly is to-day—a cornucopia of informatic about every aspect of enzyme chemistry and actio an invaluable saver of time and energy in search through the literature, a potent stimulus to th research worker himself and an immense credit all concerned in its inception, production and pu lication. The total cost of the two volumes in fou parts is of the order of £20, and this might see formidable even to the wealthier specialists. In fac it works out at rather less than 2*d*. a page, whic perhaps puts a different complexion on the matte

A. L. BACHARACH

LUMINESCENCE OF SOLIDS

n Introduction to Luminescence of Solids

y Humboldt W. Leverenz. Pp. xv+569. (New ork: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1950.) 96s. net.

PHOSPHORS are now manufactured by hundreds of tons a year, the amount having increased n-fold with the development of fluorescent lighting. elevision and radar use quantities of the order of wenty tons a year of more exacting phosphors, and here are other uses for X-ray screens, self-luminous adioactive paints, and luminous plastics and tapes or a variety of purposes. With the increasing availability in reproducible forms, since they are difficult o make on the small scale, ingenious devices employing them are likely to increase in the future.

There are two ways of developing a theory of hosphors. One that has been very popular is to egin from the ideas used for explaining the properties f semi-conductors, which lead to generalized concepts such as 'activator centres', 'electron traps', excitons', 'phonons', etc. This method treats the rystal as a whole and is helpful in attempts to nderstand how energy can pass from the nonluminescent bulk to particular centres from which mission occurs. The other method is to emphasize the essentially atomic or molecular nature of the luminescence as shown by uranyl salts or aromatic ydrocarbons, for example, the fluorescence of which carcely changes from solid to solution, and to focus ttention more on the nature of the emitter as a hemical particle than as something irregular in the deal lattice of an 'impurity-activated' phosphor.

In early work the identification of the emitters was bscured by the fact that incredibly small amounts f impurities sometimes exerted a dominating effect; n this book Dr. H. W. Leverenz here defines ideal uminescence purity' as 99·9999 per cent and spectroscopic purity' as 99·999 per cent. There are ow signs, however, that the fashion is changing, as n other fields, with a swing away from communal lectronic physical theories to individualistic chemical nterpretations, where considerations of atomic olume and variable valency are significant.

The book is the fruit of twenty years of experience n the preparation of phosphors of all types. The uthor is an outstanding authority, well conversant with every side of physics and chemistry related to he subject, cautious, accurate and systematic. He tates, "During the alchemical infancy and haphazard rowth of the phosphor art, the resultant desultory nd greatly dispersed literature on luminescence of olids has become cluttered with confused terminologies, incorrect data, and baneful misconceptions. As an antidote this book seeks to be objective, to provide a rational terminology, and to furnish a ritical guide to the literature". In seeking for ccuracy of definitions and statement, the author has llowed his style to become somewhat ponderous. He first builds up a massive apparatus of physical heory, only to show in the end to what little quantitative purpose it can be put. After advanced considerations of energy-levels in imperfect crystals, he dismisses the simpler concept of potential energy urves as "artistically stimulating; some may incorporate verity, but they have yet to achieve practical ignificance". Finally, after all the elaborations of physical theory, he states: "At present, in the bsence of a satisfactory compilation of phosphors nd phosphor properties, it is usually necessary to enlist the aid of a phosphor expert *with broad experience* in order to assure obtention of the best available phosphor for a particular purpose".

This is an extremely valuable book for all workers on luminescence, containing matter, not obtainable elsewhere, on every aspect of theory, methods of phosphor manufacture, different types of phosphor and their detailed uses, modes of excitation, decay characteristics, etc., with a multitude of precise definitions and physical data. Although entitled an "Introduction" and therefore expressing only a fraction of the author's own knowledge and experience, it is, in fact, a very extensive and detailed account which will absorb the full attention of one coming newly to the subject. E. J. Bowen

WORLD POPULATION AND FOOD

Geography of Hunger

By Josué de Castro. Pp. 288. (London: Victor Gollancz, Ltd., 1952.) 18s. net.

OF the three historic checks on population growth —war, famine and pestilence—the last-named is being dramatically curtailed by modern techniques. The ensuing population increase is both sudden and immense, and it is presenting the world with one of the biggest problems it has ever had to face, that of providing food (and other necessities) for this rapidly increasing multitude.

The author of this book believes firmly that enough food could be produced and that only the will is lacking. He cites examples from all parts of the world to show that malnutrition and frank hunger are widespread even now; but he lays the blame for this squarely at the door of Western European civilization with its domination over the 'backward areas'. Much of his criticism is valid; but the exploitation of man by man is by no means the only factor which limits the world's food supply, and no one should read this book without also reading Vogt's "Road to Survival" and Cook's "Human Fertility".

The author dismisses as "alarmist" those who press the need for a voluntary control of population increase to replace the harsh, natural checks; but he has the grace to remind his readers that "the United States of America, using fertilizers on a scale without precedent in the history of agriculture, has already exhausted 100 million acres of land in less than two centuries of cultivation".

There can be little doubt but that many apparently successful measures merely postpone the day of reckoning while adding to the bill to be paid, and it is unfortunate that this book has been published at a time when its author is chairman of the executive of the Food and Agriculture Organization, as this gives it an air of quite unwarranted authority. (It is not, of course, in any way an official publication.) The evidence presented has been collected by means of "a widespread correspondence" and "talks with strategically placed personalities" and, inevitably, not all of it rings true. Few countries are fully documented with regard to their vital statistics, food production, economic resources, etc., and many of the figures which the author uses are, at best, no more than informed guesses; they provide a very insecure base for the rather fantastic edifice he builds upon them; but the general reader may not realize this, and false beliefs and false hopes will be engendered.

The early chapters are spoilt by a florid style of writing, of which two examples will suffice. About vitamin D, it is said that, "the sun . . . pours forth this vitamin like a divine manna from the cornucopia of the heavens", and scurvy is described as "one of the more vivid of human miseries, gaudy with blood from the hæmorrhages of its victims, the strange bruised appearance of their purple skins and the ghastly stench of their rotting gums".

The issues dealt with in this book are, as Lord Boyd-Orr says, "of the first magnitude". They are urgent and immense, and they call for care and wisdom from both men of science and politicians, if they are to be solved. The emotional approach of this book does little to help. M. W. Grant

ON GROWING OLD

Commentary on Age

By Kenneth Walker. Pp. 192. (London: Jonathan Cape, Ltd., 1952.) 12*s*. 6*d*. net.

Dr. Kenneth Walker is a distinguished surgeon; his book is part philosophy, part science and part common sense. The philosophy is philosophical in the good old-fashioned sense: it is a reflexion on the conduct of life, in one of its epochs, and the dispositions that must be made to meet its enemies, with special reference to the last enemy of all. Dr. Walker writes simply, and sometimes movingly, of the rewards and sadnesses of growing old, and skilfully dissects the inevitable disabilities of ageing from those which, arising from unpreparedness, are the punishment for an earlier spiritual improvidence. He has not much new to say, it is true, and the title of his book makes no such claim for it; but wide reading and a genial eclecticism make what is true seem manifestly true, and to do that is the chief business of the commentator. What Dr. Walker says of our ageing population and the provision that must be made for the elderly is all good sense, and with such reasonable and even-tempered advocacy it may not be too long before opinion becomes policy, and policy becomes practice.

The reader must be warned, however, that the part of the book that purports to be scientific scarcely deserves to be so described. Ominous minor errors such as the mis-spellings of the names of Ebeling, McCay and Korenchevsky, the confusion of Bogomolets *père* with *fils* and of Jacques with Leo Loeb make it all too clear that Dr. Walker is not too familiar with his original sources. It is not simply a matter of minor misconceptions, such as the suggestion that elephants may live for two hundred years, or the mayfly for but a few hours, or of the uncritical acceptance of the importance of senile dehydration, the sexual rejuvenation of *Paramecium*, or the beguiling metaphor of 'physiological time'. It is mainly that the entire treatment is in a multitude of ways inexpert and unanalytic; there is no real grasp of the problem of measuring senescence, of the importance of studying the expectation of life of wild animals in the wild, or of the degree to which the senile state is one which only domesticated animals are spared to display. More serious still, one gets the feeling that Dr. Walker is inclined to equate the analysis of the scientific problem of ageing with *ad hoc* researches into the prolongation of life.

This is harsh criticism, which may be more than half countered by the retort that the book is not addressed to a professional audience and that, except in one respect, the man of science is not likely to use it as a work of reference. The exception is Dr. Walker's appraisal of the clinical value of testicular grafting, as it had been practised by Voronoff to revive the flagging energies of the elderly. He finds that even homoio-transplants of human testes are rapidly absorbed, and is highly sceptical of Voronoff's claim to have succeeded with heterografts of testes from chimpanzees. This is useful evidence on a subject on which Dr. Walker writes with personal authority. P. B. Medawar

A FAUNA OF FARM ANIMALS

A World Dictionary of Breeds, Types and Varieties of Livestock

By I. L. Mason. (Commonwealth Bureau of Animal Breeding and Genetics, Technical Communication No. 8.) Pp. 272. (Farnham Royal: Commonwealth Agricultural Bureaux, 1951.) 30*s*.

Although complete lists and descriptions of wild animals, birds and even insects exist, no world list of the different breeds, types and varieties of farm animals has been available. The first part of this book attempts to supply this.

As mentioned in the introduction, this list requires supplementing with maps and illustrations of the breeds, and it is hoped that these may be forthcoming at a later date. It is comparatively easy to find details for improved breeds which have a herdbook; but there are a large number of native breeds in Asia and Africa about which knowledge is sadly lacking. This is required if production in the backward areas of the world is to be improved. As the title indicates, the book is a dictionary to be consulted and not one to be read; references are given, however, to papers which contain descriptions of the breed in question. The second part of the book, which gives livestock numbers and breeds by countries, together with references to publications concerning the breeds of these countries, should prove most useful to those who require a bird's-eye view of the livestock production of any area. For the temperate zones and the more highly developed areas of the world, a very good picture is presented; but, through no fault of the author, the information given for the tropical zones of the world is lamentably small, consisting of, in many cases, a catalogue of breeds only. Possibly steps already taken by the United Nations Food and Agriculture Organization to collect information for those areas may soon bring our knowledge of domestic animals on a par with our knowledge about wild species. New breeds with improved production qualities suitable for tropical areas, such as the Santa Gertrudis cattle (3/8 zebu, 5/8 shorthorn), are now being formed, and may before long drive many of the primitive breeds to extinction, as has occurred with improved breeds in Great Britain. Before this is done, these primitive breeds require study for qualities suiting them to their habitat, so that some of them at any rate may be preserved and the valuable genes they contain retained for use in the future.

The species dealt with are the horse, ass, cattle, buffalo, sheep, goat and pig. The first part gives some four thousand entries, listing the various names which have been used, and for each breed mentioned it recommends an English name. Some information about breed characters, origin and relationship to other breeds is given. John Hammond

ENGINEERING, BIOPHYSICS AND PHYSICS AT KING'S COLLEGE, LONDON

NEW BUILDING

THE new physics and engineering laboratories at King's College, University of London, were pened formally by Lord Cherwell on June 27. These iboratories have been built in the only place availble, below ground, in the space previously occupied y vaults which had been broken open by bombs uring the Second World War. The proximity of omerset House prevents any part of the building rom projecting above ground-level, and the height f the water-table determined by the neighbouring 'hames limits extension downwards. Between these vels a two-story building has been constructed, the resence of which would scarcely be suspected by nyone who, entering King's College from the Strand, rives or walks over the asphalt surface of the quadangle which forms the roof of the building. However, he laboratories are extensive and, being decorated nside in bright colours and lit by fluorescent lighting nd by a surprisingly large amount of daylight enterng from large windows on one side, suffer relatively ttle from their subterranean condition.

Both physics and engineering at King's College re distinguished by the antiquity of their foundation. 'he first professor of natural and experimental hilosophy was appointed in 1831. Charles Wheattone was made professor of experimental philosophy 1 1834 and developed the celebrated Wheatstone ridge. The College can claim to be the oldest cademic institution in England to teach experiental physics, as the Clarendon Laboratory at xford and the Cavendish at Cambridge were ounded respectively in 1868 and 1871. Later, Clerk axwell was a professor, and the high traditions of he department were maintained by H. A. Wilson, . G. Barkla, Sir Owen Richardson, Sir Edward ppleton and Sir Charles Ellis, three of whom became obel laureates.

The Faculty of Engineering, which dates from 1838, the oldest university engineering school in Great ritain and Ireland, the first professor (William osking) having been appointed in 1840, three weeks efore Lewis Gordon became professor in Glasgow.

Department of Engineering

In its beginning, the Department of Engineering t King's College included in its teaching architecture nd metallurgy. To-day, undergraduate study covers ivil, mechanical and electrical engineering, which re continued in postgraduate work together with hemical engineering. The heads of these departments re, respectively, Prof. A. D. Ross, Prof. S. J. Davies, rof. J. Greig and Mr. S. B. Watkins. It is of interest hat King's College Engineering Society, an underraduate body, is the oldest engineering society of ny kind in Britain and was founded in 1847, six ays before the Institution of Mechanical Engineers.

Most of the space for engineering in the new buildng is devoted to teaching, and comprises a new rawing office, a library, laboratories for soil mechnics and for the study of structures and mechanical ibrations, and for certain branches of electrical ngineering. The space in the old building made vailable through the provision of the new drawing office is now reconstructed as a laboratory for concrete technology.

On the electrical engineering side there are two new teaching laboratories, one for machines and one for light-current work. A new research laboratory is being equipped mainly for work on automatic control systems, and a new workshop and additional photographic facilities have been provided. The research interests of the department lie mainly in the field of electrical measurements, in particular in relation to non-linear phenomena of magnetic origin. The new laboratories include a standards room in which much of the equipment will be associated with this work.

In the Engineering Faculty the research activities are distributed throughout the individual specialist laboratories and will not be concentrated in the new building.

Physics Department : Wheatstone Laboratory

Biophysics Research. The department, under Prof. J. T. Randall, is, of course, responsible for the teaching and research in physics ; but a large part of the research is biophysical, and is concerned essentially with the solution of biological problems. To understand the nature of such biophysical research, which is somewhat unusual in a physics department, it is useful to consider its character and origin. Organization of science (for example, in university departments) naturally requires much modification in order to meet the needs of these new trends.

The increasing size of the body of scientific knowledge and lack of linkage by common theory between its parts has naturally resulted in the separation of science into various subjects, each studied in the universities by specialists in independent departments. Biology, in particular, has developed independently of physics. However, the process of the sciences separating is reversed, and re-integration becomes possible, when an all-embracing fundamental theory is developed. Such theoretical development has enabled chemistry and physics to fuse with parts of biology, thus producing the new subjects of biochemistry and biophysics, which have the complementary aspects of being both new specializations and syntheses of science. Biochemistry is a coherent subject ; but biophysics is heterogeneous and exists in many aspects and more as a trend in certain aspects of biology than as a subject in itself.

The theory behind this biophysical trend is mainly the electron theory of molecular structure, which, having already reduced much of chemistry to physical terms, now, by way of biochemistry, begins to describe and explain in terms of electrons and molecules the properties of living matter and the nature of biological processes. Application of such fundamental theory makes possible the explanation and linkage of phenomena in many fields, and, as a result, it should become easier for a scientific worker to have a measure of real understanding of several branches of science. The effect on the research worker, therefore, is to enable him to return in some ways to the comprehensive view of the natural or experimental philosopher. In fact, progress in biophysics depends largely on the development of such research workers who will have a broad approach resulting from synthesis of the traditions of physics and biology.

Physics finds application in biology, not only in the theoretical approach but also in the use of many new physical techniques. Perfected physical tools (for example, the ordinary compound microscope) may be operated by biologists, but collaboration with physicists is desirable when the information obtained by the method is essentially physical in nature as well as biological; or when the development and operation of the technique requires much physical insight. The aid that physicists can give biologists by providing new techniques is an important aspect of biophysics; but elucidation of biological phenomena in terms of molecular theory has ultimately greater significance.

These trends in certain aspects of biology have developed during the past thirty years—in most cases not under the name of biophysics—in university departments of chemistry, biochemistry, physiology, etc. It has also often been necessary to create new departments of biophysics, research units and research institutes.

Owing to the complicated nature of biophysical problems, it is generally desirable to approach the same subject from many different angles and by use of a wide range of techniques. This is best achieved by mutually sympathetic and understanding specialist biologists, biochemists, physicists and hybrid scientists working in one laboratory and allowing their efforts to unite. A biophysics laboratory will tend to be large because it must contain both a large personnel and an exceptionally wide range of facilities.

To expand a physics department in a biological direction it is necessary to go outside the normal university departmental framework. Biology graduates can scarcely hold posts as teachers of physics, or *vice versa*. At King's College this difficulty is overcome by the inclusion in the Physics Department of a Medical Research Council Biophysics Research Unit, which contains scientists and technicians other than physicists. Apparatus has been provided by King's College, the Medical Research Council, the University Grants Committee and the Rockefeller Foundation. Further staff and apparatus have been provided for by research fellowships and grants from the Nuffield Foundation, the British Empire Cancer Campaign, the Rockefeller Foundation, and Imperial Chemical Industries, Ltd. Research students are physics graduates and biologists, and biophysics is a recognized subject in the University of London for postgraduate study. When physics graduates become research students in biophysics, they are required to attend courses in biology. In order that biophysicists should preserve a rigorous approach to the main branch of science in which they have graduated, the research workers who are not on the physics teaching staff of King's College usually contribute to the teaching in other appropriate departments of the College.

The biophysics research at present involves about twenty-four graduates, including four biologists and two chemists, and there are twenty-seven technicians, both biological and physical. Dr. Honor B. Fell, director of the Strangeways Laboratory, Cambridge, acts as senior biological adviser to the Medical Research Council Unit.

One aspect of the biophysical research of the Department is concerned with the structure and function of various biological fibrous molecula systems. Collagen provides a favourable opportunit of studying the structure of protein in relation to it function and mode of formation. Connective tissu composed of collagen grows with a quasi-crystallin structure from smaller protein units in solution, an the resulting fibres have a very great tensile strengt correlated with a highly oriented system of chemica bonds.

The fibrous molecule of deoxyribonucleic acid i often supposed to have a special function in relatio to protein synthesis. It has been found possible t crystallize the pure substance in the form of fibre and then to determine, by X-ray diffraction, man of its structural characteristics, which can also b shown to exist in living sperm cells and in the nucle of growing cells. The structural relation of protei to nucleic acid is also being elucidated, and this ma cast light on the mutual role of nucleic acid and protein in growth, and the relation of these molecula patterns to specific chemical differences associate with gene action.

The other main aspect of the biophysical researc is the development and application of physica methods to determine the distribution of chemica substances in growing cells. Ultra-violet, infra-re and interference microscopes are used to measur the concentrations of nucleic acid, protein and othe substances. Thus, from the cytochemical side, th functional relationship of nucleic acid and protein i studied, and this connects with the molecula structure approach to the same question. Th development (by use of a microscope interferometer of successful reflecting microscopes for this work ha involved much physical study.

On the biological side, the department has all usua facilities, including an animal room and tissue-cultur laboratories. There are two time-lapse phase ciné microscopes in 'hot-boxes'; a 35-mm. camera on eac biologist's microscope; cytological freeze-dryin equipment; several ultra-violet microscopes; a high power ultrasonic generator; and a flying-spot microscope.

On the more physical side, there are two electron microscopes and a 400-kV. instrument nearin completion. Three ultra-violet and two infra-re microspectrometers together with five reflectin microscopes are at present in use. A semi-fine-focu X-ray tube and two fine-focus tubes are used i conjunction with several microcameras and a long spacing diffraction camera.

Biochemical facilities include cold rooms at 0° C and −20° C.; an ultracentrifuge; electrophoresi apparatus; and a 12-litre centrifuge, ultra-viole spectrophotometers, etc.

Theoretical Physics. A strong theoretical grou of about twelve workers has been engaged unde the direction of Prof. C. A. Coulson on applications of wave mechanics and statistical mechanic The theory of the chemical bond has been develope and applied to questions of the chemical reactivit of molecules, the stability of crystal structures, biological properties of molecules such as cancer producing chemical compounds, electrical and magnetic properties of metals, etc. A second aspec of the work concerns properties of electrolytes an colloidal solutions, including the theory of electrophoresis. The activity of the theoretical physic group at King's College may be judged from th fact that more than one hundred papers have bee published during the past five years.

Experimental Physics. Apart from biophysics, there e several distinct physics research groups in the heatstone Laboratory.

One group is studying effects produced by clear radiations and light on various crystalline sulators such as diamond. Variations in the texture diamonds have been shown to cause wide changes some of their physical properties. This work has e dual purpose of developing radiation detectors nich utilize such effects, and of increasing knowdge of how energy is transported and converted in sulators and semi-conductors.

Another group is concerned with the temporary stortions produced in the earth's electric field due thundercloud disturbances. The relation of the opagation of this field distortion, the wave-form, d its frequency analysis are studied by means of ulti-tube cathode-ray wave-form recorders and dio spectrometers installed on the roof of the College.

An electronics group is concerned with the development of high-speed electronic-analogue computing chniques and their applications to a variety of ysical and biophysical problems. Two high-speed mputing instruments have been built. Techniques e also being developed for the study of the central ervous system from the point of view of information eory.

In connexion with biophysical applications of ectroscopy, investigations of the fundamental relaon of optical properties to molecular structure are eing made by a spectroscopic group. The ultra-violet d infra-red absorption of small molecules and ystals of known structure is being measured by eans of high-dispersion equipment using polarizers, flecting microscopes and automatic recorders. undamental studies in the vacuum ultra-violet are so in progress.

M. H. F. Wilkins

LONG ASHTON RESEARCH STATION

OPEN DAY

AT the University of Bristol Agricultural and Horticultural Research Station's Open Day on uly 15, several items of particular scientific interest ere demonstrated. In the Pomology Section, Dr. . C. Luckwill dealt with fruit-thinning sprays conaining α-naphthalene acetic acid. These, applied to pples within three or four weeks of petal-fall, induce ed abortion, and consequently an increased drop of oung fruits. The concentration required to give atisfactory thinning is affected by the variety, the itial set of fruitlets and the stage of development t the time of spraying. The method, therefore, annot yet be safely recommended in commercial pple growing.

Paper chromatography is being employed at Long shton in the study of the natural auxins controlling ruit development. An exhibit showed some of the iological tests employed for locating the position of he auxins on the chromatograms. These include a odification of the coleoptile cylinder test and the *oleus* petiole abscission test.

In the plant nutrient investigations under the irection of Dr. E. J. Hewitt, specific visual symptoms n the cauliflower plant were used to demonstrate its olybdenum requirements in the presence of nitrogen pplied respectively as nitrate, nitrite, ammonium or urea. Nitrate consistently induced a characteristic mottling, absent from plants given the other treatments.

A survey of the copper, zinc and molybdenum requirements of large-seeded legumes demonstrated that the seed reserves in dwarf, runner and broad beans and in peas could provide sufficient molybdenum for one year's growth but rarely for two. Seed reserves of these crops also mitigated the effects of copper and zinc deficiencies. In comparative trials of water purification methods in the study of molybdenum, copper and zinc requirements, the behaviour of test crops showed that rainwater demineralized by a suitable ion-exchange resin was similar to glass-distilled water.

Iron deficiency was induced in sugar-beet by excess of copper, zinc or manganese. The degree of chlorosis produced was increased by extra molybdenum and, outstandingly, by copper.

The exhibits dealing with insecticides included a demonstration by Mr. S. H. Bennett (working in collaboration with Dr. W. D. E. Thomas) of biological methods using chrysanthemum plants infested with *Macrosiphoniella sanborni* for tracing the movement of octamethyl pyrophosphoramide (schradan) through the plant. This method used in conjunction with radioactive tracer techniques permitted accurate study of the translocation of the insecticide.

Dr. R. J. W. Byrde, of the Mycology Section, demonstrated the effect of winter spray treatments in inhibiting sporulation by *Nectria galligena* (causing apple canker) and *Sclerotinia fructigena*, the brown rot fungus. The effect on *Nectria galligena* was sufficient to reduce subsequent leaf scar infections; but in *S. fructigena* the supply of spore inoculum could be built up sufficiently quickly to outweigh the effect of the winter treatment.

In an exhibit illustrating improvements in spray nozzles, Mr. N. G. Morgan and Dr. H. G. H. Kearns showed two standardized designs. The first was a light-weight all-purpose ¼-in. B.S.P. nozzle, with interchangeable parts for high- or low-volume spraying at low pressures (30–75 lb./sq. in.), suitable for light lances, ground-crop booms or air-flow machines. The second was a ⅜-in. B.S.P. nozzle intended mainly for high-pressure (200–400 lb./sq. in.) spraying of fruit trees by means of hand lances or spray masts.

The exhibits of the Cider and Fruit Juices Section (under the direction of Dr. A. Pollard) were concerned both with the practical aspects and with some of the more fundamental work at present being undertaken on cider and apple juice production. In an exhibit emphasizing the microbiology of cider making, photomicrographs illustrated the yeasts and bacteria capable of giving rise to disorders of cider. The latter included 'sickness' bacteria and lactic rods responsible for the condition known as 'ropiness'. The use of acetic bacteria in the production of cider vinegar was the subject of a practical demonstration.

An exhibit of unfermented apple juices illustrated oxidation phenomena during processing and storage. The addition of small amounts of sulphur dioxide at the time of milling the fruit was shown to inhibit the initial rapid oxidation of polyphenolic components which normally occur, the amount required exhibiting wide variation according to fruit variety. Adequate exclusion of oxygen from the bottled and pasteurized product was shown to inhibit the slower oxidative changes which occur on storage.

The result of field trials with selected varieties of cider apples grown as bush trees was illustrated by

Dr. Luckwill and Mr. R. R. Williams. Average annual yields over a period of three years have ranged from less than one to over thirteen tons per acre, depending chiefly on the variety. These intensive methods of cider fruit production have brought their problems of pollination, and work is in progress to determine the self- and cross-fertility of the recommended varieties. A provisional list of the triploid varieties of cider apples was displayed. R. W. Marsh

STRUCTURE OF ELASTIC TISSUE

By Dr. D. A. HALL, Dr. R. REED* and Prof. R. E. TUNBRIDGE, O.B.E.

Departments of Medicine and of Leather Industries, University of Leeds

ELASTIC fibres are described in standard histological texts as being yellow in colour, highly refractile and as exhibiting considerable elasticity[1]. The fibres run singly, branch freely and anastomose with one another and can be differentiated by selective stains such as acid orcein and resorcinol fuchsin. They form the major component of the elastic tissue of aortic media and ox ligamentum nuchæ. It has been shown[2] that the apparent increase in elastic staining in certain pathological conditions of the skin may not necessarily be associated with similar increases of elastic fibres, as identified under the electron microscope, but may be due to the presence of altered collagen. Such anomalies in the basic criteria for the identification of elastic fibres and elastin led us to study the morphological and chemical characterization of elastic fibres, and the present communication summarizes our observations of human aortæ and ox ligamentum nuchæ.

Histological examination has confirmed the findings of Benninghoff[3] that there are in the media of human aorta two components, fibrils and lamellæ, to which the name elastin could be given on the basis of their staining properties. By contrast ox ligamentum nuchæ consists solely of large fibrils running parallel to the long axis of the fibres. Morphological differences are also evident under the electron microscope. Disregarding the fibrils of collagen which are a characteristic and easily definable component of all elastic tissue, the aortic media contains ill-defined branching fibres, some of which are apparently made up of still smaller fibres embedded in an amorphous matrix. The large lamellæ observed under the light microscope contain similar elements. On the other hand, ox ligamentum nuchæ consists solely of dense broad fibres of circular cross-section arranged in parallel formation and exhibiting no branching.

Both tissues react similarly when treated with pancreatic elastase. Some of the cementing matrix is first digested, the fibres becoming less opaque and collapsing, revealing an array of fine fibrils, lying roughly parallel to the long axis. These fibrils are quickly broken down into small particulate material. Thus the action of elastase points to a morphological similarity between the two tissues, although under the light microscope considerable differences are apparent.

The chemical evidence is similarly confusing. The majority of data previously available had been obtained from studies on ox ligament and had shown that elastin differed from most albuminoids in the it was remarkably insoluble in the normal solvent for proteins, while those reagents capable of dissolvin it apparently did so only with considerable degrada tion. Total analyses have been made by Richar and Gies[4], and amino-acid analyses of preparation believed to be pure elastin have also been made b Stein and Miller[5] and by Neuman[6]. Stein and Mille used either boiling 40 per cent urea solution fo protracted periods or short treatment with water t remove associated proteins, and reported that th analyses of the materials remaining were identica Later workers have used the simpler method o preparation to minimize degradation of the protein but it has recently been reported by one of us (Hall[7] that treatment of human elastic tissue with hot wate or acetic acid, although previously presumed adequat for the removal of collagen, does not free th preparation from all proteins other than the elasti of Stein and Miller. A fraction remains resemblin collagen on analysis, having both basic amino-acid and hydroxyproline in excess of the accepted value for ox ligament elastin, but having neither th striated structure nor the solubility properties o collagen. Hence all analyses of tissue for elasti content based on the separation of elastin as fraction insoluble in water or acetic acid[8,9] will giv erroneously high values in tissues such as huma aorta where the extra component appears to b present. The acetic-acid-resistant protein can be removed from elastin by prolonged treatment with dilute solutions of urea, hence the method of Neuma and Logan[10] should give more reliable results wit human tissue. The material remaining after the removal of collagen and the extra component has an amino-acid analysis identical with elastin preparations obtained from ox ligament by the action of acetic acid alone. This is further evidence of the complexity of human elastic tissue as compared with that from ox ligamentum nuchæ and, at the same time, of the possible existence of a common component.

The insolubility of elastin in boiling 40 per cent urea solutions, as claimed by Stein and Miller[5], has been shown by Hall[7] to be relative and dependent only on the ratio of urea to elastin. The product of such a reaction with urea is a soluble protein which from preliminary ultracentrifuge and osmometry observations appears to be of low molecular weight and which from electrophoretic data migrates as a single peak over a pH range of 2–10. Further, no free amino-acids have been identified in the dialysate; but, most significantly, polysaccharide and acid are released during solution. This protein species is also reversibly denatured by heat, the temperature at which this is brought about varying with pH and ionic strength of the environment and being lowest (14° C.) at pH 2·8 and at an ionic strength of μ–0·2. This soluble protein, therefore, is similar in some respects to that reported by Adair, Davis and Partridge[11] as being produced from elastin by the action of 0·25 M oxalic acid. Their protein was a mixture of two fractions, one with a molecular weight of 84,000 showing thermal denaturation and the other of much lower molecular weight and not denatured by heat. A further significant difference is the short duration of the oxalic acid reaction and the reported presence of acidic amino-acids in the dialysate, phenomena which Adair *et al.* attribute to incipient hydrolysis of the elastin molecule. Recently, Wood[12] has demonstrated that other methods, such as prolonged boiling with 0·1 N sodium hydroxide or eatment with performic acid at 18° C., can be used r the production of similar soluble proteins and at, in addition, polysaccharide and sulphuric acid e liberated.

---

* The electron microscopic studies were carried out while Dr. Reed was on the staff of the Department of Biomolecular Structure of this University, and the authors would like to thank Prof. W. T. Astbury for the facilities provided.

Elastin can be digested by the enzyme elastase[13]. ur initial observations appeared to preclude the istence of a component common to all elastic tissue nce there was a gross difference between the susptibility of human aorta and ox ligamentum nuchæ attack by the enzyme. Little, if any, of the gament was dissolved at pH 10·3 and under the nditions described as optimum by Balo and Banga[14]. e have shown that this phenomenon is due to adequate buffering. Appreciable quantities of lphuric acid are liberated by the action of elastase human tissue, especially at high pH values, hereas over a similar range of pH the amount of id released from ox ligament is much less. Given lequate buffering, it has been shown that elastase as the same shape of pH sensitivity curve for both ibstrates with an optimum pH value of 8·55. The nount of acid liberated from aortic tissue under nditions of inadequate buffering at an initial pH 10·3 was sufficient to lower the pH to the optimal alue of 8·55, whereas with the ligament an initial H of as low as 9·5 was needed before the required epression could be attained. The quantity of acid berated was directly proportional to the amount of astin passing into solution during the dissolution of e first half of the tissue. At this point, however, e whole of the acid had been released and the maining protein passed into solution without any rther lowering of pH.

Collagen-free human elastin preparations, treated ith urea to remove the extra component, show rogressively increasing susceptibility to enzyme ttack. With a concentration of urea suboptimal for lution it is possible to remove the extra component ithout affecting the solubility of the remaining lastin. Material which has been completely taken ito solution by means of urea, and then reprecipated from solution by acetone, shows a far greater ate of dissolution under the action of elastase and a arked increase in its degree of solubility in buffer lution. Ox ligament, which dissolves in urea lution over a much shorter time range, shows little icrease in susceptibility to elastase until final lution occurs.

Before discussing the possible structure of elastic bres we would direct attention to the following bservations:

(1) The soluble proteins obtained from elastic issue by all the chemical methods show the property f reversible heat denaturation; but the soluble rotein produced by the action of elastase does not.

(2) Amino-acid analysis of the proteins obtained om both aortic and ligament tissues, either by reatment with urea or oxalic acid, are similar to the reviously accepted values for 'elastin'.

(3) Urea solutions of elastic tissue contain no free mino-acids, but such compounds are present in xalic acid solutions.

(4) Polysaccharide and sulphuric acid are liberated y the action of those reagents which produce the oluble protein material.

(5) The action of elastase on human aortic tissue nd on ox ligamentum nuchæ is similar from a norphological point of view. Fine fibrils are embedded n an amorphous cement substance in both tissues, nd removal of the latter results in the collapse of he structure.

(6) Solutions of elastic tissue in urea show low viscosity and no streaming birefringence, hence they may contain a corpuscular unit similar to the G-elastin postulated by Banga[15].

(7) The total amount of polysaccharide in the tissues is small, approximately 2 per cent in aorta and 0·5 per cent in the ligamentum nuchæ.

It is therefore reasonable to suppose that part at least of the elastin system is made up of linear aggregates of a corpuscular protein unit of low molecular weight. To this extent we agree with Banga[15], who considers that fibrils of elastin (*F*-elastin) are built up from repeating units of *G*-elastin, entirely analogous to the *G*–*F* transformation of the muscle protein actin; but so far there is no evidence to identify the hypothetical *G*-elastin with the units we have observed. Moreover, Banga's concept of *G*- and *F*-elastin precludes the involvement of such units in mixed mucoprotein chains (see below), and therefore we think it inadvisable to use the name *G*-elastin for these structural units. On the other hand, to use the name elastin would be equally confusing, since the word has a different meaning for the chemists and for the histologists. We suggest as a temporary expedient that these corpuscular units should be proelastin, analogous to procollagen[16], the soluble protein derived from collagenous tissues. There is, however, as yet no evidence that proelastin exists in the free state in elastic tissue.

The main difference between our observations and those of previous workers is the finding that polysaccharide and sulphuric acid are intimately associated with protein in elastic tissue. It is significant that polysaccharide is liberated simultaneously with protein whenever the tissue is degraded, and this points to the association of acid, polysaccharide and the proelastin as being a necessary condition for tissue stability. To postulate linear chains of polysaccharide arranged in parallel association with aggregates of proelastin would be more in accord with present knowledge of muco-protein systems; but it is difficult to see how such an arrangement could bring about the high degree of stabilization observed. As a possible explanation we would suggest the presence of mixed mucoprotein chains each of which is formed by proelastin units joined by polysaccharide molecules and that these chains are essentially the stabilizing cement material surrounding chains of linearly aggregated proelastin. A suitable name for this species would be elastomucin. In our view, therefore, elastic staining tissue consists of linear aggregates of proelastin protected by material consisting of similar units held together by union with polysaccharide. The ratio of polysaccharide to proelastin has not yet been determined accurately, but five moles of acid including both sulphuric and possibly uronic acids are associated with each proelastin unit.

The dual nature of elastin seems to follow from the fact that during the action of elastase all the acid is liberated during the dissolution of only half the protein. It also accounts for the presence of amorphous and fibrous material as revealed by the electron microscope.

The doubt expressed by Banga[15] as to the function of elastase is substantiated by our observations. We suggest that elastase is not a proteolytic enzyme, but rather a mucase. It would therefore attack only the elastomucin chains liberating the proelastin therefrom. Once the stabilizing effect of this elastomucin is removed, however, the remaining proelastin would be released by direct solvation from the chains containing no polysaccharide. This mechanism would account for the liberation of all the acid during the first half of the enzyme reaction and, if the fine fibrils observed in the electron microscope during the initial stages are aggregates of pure proelastin, would also explain their rapid disintegration. Proteolytic enzymes such as trypsin which have been shown to digest elastic tissue after prolonged treatment must be assumed to attack the proelastin units themselves.

The proposed structure would also account for the liberation of protein units of similar properties by the prolonged action of reagents such as alkali and performic acid, capable of disrupting the polysaccharide, since similar units of proelastin could originate from both the cement material and the fibrils. A reagent favouring polypeptide hydrolysis such as oxalic acid would be expected to have a different action, as indeed is the case. Chemical reagents might be more drastic in their removal of polysaccharide than the enzyme, and the retention of sugar residues masking the ends of the proelastin from the cement material, in the case of protein solutions prepared by elastase, could preclude the thermal denaturation of the whole preparation.

Thus we suggest that there is considerable evidence in favour of the existence of two common entities in the elastic staining fibres of human aorta and of ox ligament.

The polysaccharide—elastomucin—content of aorta is higher than that of ox ligamentum nuchæ, and this finding is supported by the presence in the aorta of sheets of amorphous material at the e.m. level and of the lamellæ at the light microscope level. The smaller concentration of elastomucin in ligament would explain the more rapid rate at which this tissue finally passes into solution, since little mass would be dissolved during the earlier removal of the cement substance. Schultz[17] in 1922 suggested that the staining capacity of elastic tissue was due to the impregnation of elastin by mucin, which he identified as the 'chromatropic ground substance' present in many tissues. Our proposed structure gives a rational foundation for these deductions which were based solely on histological observations.

Whether any enzyme function is associated with the linear aggregation of proelastin, as is the case with actin, is unknown. It is significant, however, that Banga and Nowotny[18] have reported the presence in aortic tissue of an ATP-ase different from the muscle enzyme and which falls in amount as the elastin content of the aortic media decreases with increasing severity of arteriosclerosis.

A knowledge of the structure of elastic tissue is essential for an understanding of clinical problems. Balo and Banga[19] have applied their studies of elastase action to the problem of arteriosclerosis and have suggested that the degeneration of human elastic tissue is brought about by the enzyme elastase, which they had shown to be present in beef pancreas. Further, the enzyme was thought to be controlled by an inhibitor present in the sera of normal persons, but absent from those of patients with vascular degeneration. We have been unable to obtain elastase from normal human pancreas processed in an identical fashion to the hog and beef pancreas used for the routine preparation of the enzyme. This observation has been confirmed by a personal communication from Mr. E. Levin, of the Viobin Corporation, from whom the hog pancreas used in this work was obtained. It may be that, in the human, elastase is secreted in organs other than the pancreas, but it is more likely that the whole question of elastomucin involvement in arteriosclerosis is far more complex than that of a simple enzyme/inhibitor system, and more studies are needed, especially into the mucoid/protein interrelationship, in order to assess the changes involved in vascular degeneration. Again, in the present communication we have ignored the possible participation of lipoid as a tissue stabilizer, but in view of the changes associated with arteriosclerosis, no hypothesis would be adequate that ignored so important a factor.

We would like to register our indebtedness to Mr. T. J. Bowen for physical observations and to Dr. F. Wewalka, of the 1st Medical Clinic, Vienna, for help in some of the initial observations on the elastase reactions; also to Messrs. A. Millard and G. D. Coulson and Misses I. Rennie and B. Stannard for technical assistance. We also wish to acknowledge the gift of samples of elastase of high purity from Prof. I. Banga, Budapest.

OBITUARY

Dr. J. C. James

John Charles James was born at Harrow in 1920. He passed through Harrow County School to Queen Mary College, London, where he took first-class honours in chemistry in 1940. After a period in the laboratories of the London Passenger Transport Board, he became a research student under C. W. Davies at Battersea Polytechnic (where he was made lecturer in 1945), and was awarded the Ph.D. degree by the University of London in 1947. Since 1948 he had been a lecturer in chemistry in the University of Glasgow.

Deriving from his training at Battersea, his earlie work, and most of his published work, involved the accurate measurement of electrolytic conductivities from which were elucidated various ionic interactions in solution. During the past two years he had become interested in the polarography of non-aqueous media and in the double-layer capacity at electrode surfaces he and his students were opening up several very promising lines of research in these related fields James was an able and industrious experimentalist ingenious in adapting electronic techniques to the tudy of electrochemical problems. He had also ecently collaborated in the first reliable determination of the dielectric constant of anhydrous sulphuric acid, proving this important quantity to be not much higher than that of water. Only the first-fruits of all his later work have yet been published.

Though of a quiet disposition, James was a good and witty lecturer, very popular with his students, and well liked by his colleagues. He was unmarried. His untimely death in a mountaineering accident in the Jotunheim, Norway, on July 9 is a great loss to electrochemistry in Britain. J. C. SPEAKMAN

NEWS and VIEWS

Parliamentary and Scientific Committee: Deputation to the Lord President of the Council

A DEPUTATION from the Parliamentary and Scientific Committee, including Lord Samuel (president), Lord Waverley (past-president), Sir Ralph Glyn (deputy-chairman) and Mr. M. Philips Price (vice-president), which waited on Lord Woolton, the Lord President of the Council, on July 28, while welcoming the indications in the speeches of Lord Woolton and Lord Cherwell in the debate in the House of Lords on June 11 that the Government recognizes the urgent importance of exploiting discovery and research as rapidly as possible and of a much closer liaison between science and industry, asked for further information as to the specific action the Government proposed to take in the immediate future, especially in so far as such action would make a valuable contribution to productivity and the balance of payments crisis. Further information was also requested as to the action the Government proposes to take to meet the very serious criticism of the last report of the Advisory Council for Scientific and Industrial Research, especially in regard to the recruitment of staff and the execution of the Department's Building Programme. In this connexion the Parliamentary and Scientific Committee urged that it was false economy to hold up essential developments in the country's scientific and technical resources. Research must be based on reasonably firm budgetary expectations for several years ahead, and sudden and unexpected limitations or cuts caused more than a proportionate retrenchment. The deputation also urged the extension of the co-operative research scheme to research in veterinary medicine and agriculture and asked for further information as to the steps to be taken to build up a technological institution of university rank and to increase the financial assistance available for selected technical colleges.

The deputation also indicated the Committee's strong endorsement of the main conclusions in regard to scientific man-power of the last report of the Advisory Council on Scientific Policy, and also represented to Lord Woolton that the facilities for the publication of original papers and abstracts in the field of chemical sciences also called for inquiry and action by the Government. Some replies received in reply to a question as to the extent to which industry made effective use of the results of scientific research and any obstacles to the utilization thereof, included in a questionnaire circulated by the Committee prior to the House of Lords debate, suggested that the absence in Britain of an efficient abstracting journal or journals was a major obstacle and that there was a case for further support from the Government for scientific publication generally. Defective liaison services, the lack of trained men both on boards of directors as well as in production, difficulties experienced in obtaining licences and delivery of items of plant, financial problems arising out of plant obsolescence and taxation policy were also contributory factors, as well as the general backwardness of some industries. Lord Woolton expressed his keen interest in the points raised and promised to give them careful consideration.

Wool Industry Research Levy

AN Order increasing the wool industry research levy was approved by the House of Commons on July 24. The amount of the levy depends on both the employment in the industry and its consumption of raw material. Both have declined, and the increase has been requested by both sides of the industry, by the Wool Textile Delegation and by the National Association of Unions in the Textile Trade, and it was estimated by the Parliamentary Secretary to the Board of Trade that the amended rate would have yielded £70,000 in place of the £48,000 actually collected during the first six months of this year or the £114,000 produced by the first year of the levy approved in October 1950. Of the £48,000 collected this year, £31,000 was based on the employment unit and £17,000 on the supply and consumption of fibre. The Parliamentary Secretary expressed himself as satisfied with the programme of research conducted by the Research Association and stated that the £100,000 required to qualify for the grant from the Department of Scientific and Industrial Research was regarded as adequate for the programme in mind. Some concern as to the value of that programme was expressed in the debate, notably by Mr. Mikardo, who urged that the most forward-looking and imaginative research was being done not in the Research Association establishments but in industry. He questioned whether the research association was devoting sufficient attention to what he called the fundamental problems of the industry, and asked whether the distribution of expenditure on research between the research association, the universities and the technical colleges was that most appropriate to enable the industry to make the best use of scientific knowledge. Mr. Mikardo was as concerned as other speakers in the debate that there should be adequate expenditure on research and the fullest possible utilization of its results by the industry. The distribution of research effort is not a matter for the Board of Trade, however, and Mr. Mikardo scarcely made his case sufficiently specific to warrant the Department of Scientific and Industrial Research setting up a further survey panel from what he said alone.

United Nations Resolution on Indigent Aliens and Refugees

ON August 9, 1951, at its thirteenth session, the Economic and Social Council of the United Nations adopted a resolution directing attention to the report on assistance to indigent aliens prepared by the Secretary-General at the Council's request and re-affirming its recommendation that governments should not expel or deport aliens solely on the grounds of indigency or becoming public charges. The resolution recommended governments to accord to aliens lawfully in their territory the same measures of public assistance as are accorded to their own nationals and to give effect to the principles enunciated in the Secretary-General's report in any legislation or administrative action required. The Department of Social Affairs of the United Nations has now issued a pamphlet entitled "Study on Assistance to Indigent Aliens" (pp. 81. New York: United Nations. London: H.M.S.O., 1952. 50 cents or 3*s.* 9*d.*), and this publication embodies the analysis and conclusions contained in the Secretary-General's report as well as some current data and information. Besides the general conclusions drawn from the survey, which led to the resolution already quoted, those reached by the Social Commission and the Economic and Social Council are also indicated. Appended are the texts of some existing conventions or agreements, including the Model Convention on Assistance to Indigent Aliens approved by the Council of the League of Nations in May 1938, the Convention which was concluded between Denmark, Finland, Iceland, Norway and Sweden in January 1951, and that on the Status of Refugees adopted by a United Nations conference on July 25, 1951.

Survey of Physiology in the United States

THE American Physiological Society, under contract by the National Science Foundation, is undertaking a study to determine the present status in the United States of research and education in physiology, including an inventory of available scientific workers, facilities, and institutional and communication problems, and an appraisal of how progress in physiological research relates to other scientific fields and the national welfare. The project has been sponsored by the Foundation, partly because of the central importance of physiological research to all sciences, but primarily to test the value of such a survey-inventory in assisting the Foundation in developing a national policy for science and research in the United States. The contract will be administered for the Foundation by Mr. John Field, assistant director for biological sciences. The survey-inventory will be conducted in two parts, the first being a pilot study, which has already begun and is expected to last for seven to nine months, and from this will be developed the pattern for a more detailed full-scale investigation, which, it is anticipated, will last for an additional eighteen months. The full-scale study will include such problems as the historic development of physiology as a science, present conditions and trends, research and educational facilities and personnel, and the policy for the dissemination of information, communication and publication in physiological work. The pilot phase of the study, costing 33,500 dollars, is under the direction of an honorary central committee, appointed by the American Physiological Society, and the committee has appointed Dr. Orr E. Reynolds, on leave of absence from the Office of Naval Research, to serve as executive director on the pilot project.

Moving a Factory

MR. ROY LEWIS, joint author of the recently published highly successful book "The English Middle Classes", has written a fascinating account of the resettlement of a factory and its workers in the first of Britain's new towns. The factory, Sunvic Controls, Ltd., was formerly housed in a "warren of workshops" in Long Acre, Covent Garden, and was rapidly developing the highly skilled business of producing instruments for temperature, electrical and other forms of control. With the rearmament programme, expansion of facilities became essential and urgent in the nation's interest. A new factory was needed; but it was essential to keep at least a nucleus of the skilled staff together. In Harlow new town the requirements were ideally met; the Development Corporation was glad to get a rapidly developing business for its industrial estate. The directors of Sunvic wished to move the whole factory from Long Acre to Harlow, and put the proposition to the staff. Despite many obstacles about 70 per cent of them elected to move and, in his booklet, Lewis describes how these and unexpected difficulties were overcome, how personal problems were resolved and a new team spirit at Harlow was created. The booklet, which may be obtained from Sunvic Controls, Ltd., No. 1 Factory, Harlow, Essex, admirably describes a sociological experiment which is of the greatest significance in the re-distribution of urban populations from over-crowded cities.

Aslib: Report for 1951

THE annual report of the work of Aslib for the year ended December 31, 1951 (pp. 22; London: Aslib, 1952), records an increase in membership from 1,038 in 1950 to 1,219, the largest percentage increase—thirty—being in the industrial and commercial membership. Besides the annual conference at Ashorne Hill in October, for which many applicants had to be refused, a successful conference was arranged by the Scottish Branch in May, and one arranged by the Northern Branch at Birmingham in June led to the inauguration of a Midlands Branch in September. The Northern Branch also arranged a successful meeting at Leicester, and six London meetings were held during the year. A number of special groups were also established during the year, covering aeronautical engineering, textiles, economics, and food and agriculture. The report includes an extended analysis of the work of the Information Bureau and Library, which handled 3,521 inquiries during the year, an increase of 33 per cent on 1950, apart from 1,236 loans from the Aslib library. Of these inquiries, 1,255 were requests for inter-library loans; and, of the 1,690 telephone inquiries, 464 were for complete bibliographical references of published works and 379 for locations, not necessarily for loans. Of 576 postal inquiries, the most numerous were for complete bibliographical references of published works or references on a specific subject (129 each) and for special library routines, training, etc. (106). By the end of the year, 3,500 translations had been recorded in the index of unpublished translations.

Petroleum Consumption and Refinery Production in Great Britain during 1951

THE Petroleum Information Bureau (on behalf of the United Kingdom Petroleum Industry Advisory Committee) has released statistics of oil consumption and refinery production in Great Britain during 1951, which show an increase in total consumption of all products of 1,611,137 tons above that of the previous year. When it comes to output of finished products from the refineries, the figures are even more impressive: 16,430,025 tons in 1951, as against 9,283,752 tons in 1950. This actually reveals the intensive development of refinery capacity which has aken place in the past twelve months or more in ccordance with the refinery expansion programme Great Britain. Production of aviation and motor pirit was 2,923,181 tons as against 1,477,955 tons in 950; again, nearly half the output of refinery roducts was fuel oil—7,649,982 tons during 1951 nd 3,805,198 tons during 1950. The refineries are rocessing almost entirely Middle East crude oil, hus saving dollar currency, and, in any event, the ncreased output represents a substantial saving in ost of the finished products.

rchæology in Greece and Cyprus during the Year 1950–51

THE survey, "Archæology in Greece, 1950–51", by . M. Cook, to which is appended "Archæology in yprus, 1951", by A. H. S. Megaw, is published both n the annual report for the session 1950–51 of the ritish School of Archæology at Athens (pp. 60; rom 9–13 George Street, London, W.1; 1952) nd in *Journal of Hellenic Studies*, 52 (1952). The econd World War and its consequences have had ne good effect in classical archæology, namely, hat there has been less excavation and more study f what had already been excavated. Hence these wo surveys, which are limited to field-work and nds of objects, are less sensational than sometimes n the past. The energetic Orlandos is repairing and estoring ancient and medieval buildings in many arts of Greece. The Americans continue their model xploration of the Agora (or public centre) of ancient thens, the greatest and most solidly productive ndertaking of classical archæology; it now seems hat there is below the Agora a large cemetery of the ate Bronze Age. Of other excavations the most seful is that of Old Smyrna, where the Turks and ritish have found remains going back to the Early ron Age; this is important for the date and nature f the Greek colonization of the coast of Asia Minor. lsewhere, expeditions have produced finds interesting in themselves, but of less general relevance. There still a tendency to excavate without good reasons; erhaps, in this respect, rising costs will prove a lessing.

olonial Service: Recent Appointments

THE following appointments have recently been ade in the Colonial Service: P. Adames (agricultural fficer, Sierra Leone), principal agricultural officer, ierra Leone; E. G. Giglioli (assistant agricultural uperintendent, British Guiana), agricultural superntendent, British Guiana; T. S. Jones (agricultural fficer, Sierra Leone), senior agricultural officer, ierra Leone; C. H. B. Williams (deputy director of griculture (crop husbandry), Trinidad), director of griculture, Trinidad; A. Cawley (deputy director, eological Survey, Nigeria), director, Geological urvey, Uganda; C. E. W. Hoar (pathologist, igeria), pathologist, Uganda; R. E. Alvares ssistant pathologist, Hong Kong), pathologist, ong Kong; J. P. Henderson (meteorologist, East frican High Commission), assistant director, East frican Meteorological Department; P. I. R. acLaren (fisheries officer, Nigeria), fisheries officer, ame and Tsetse Fly Department, Northern hodesia; Ong Chin Ghee (senior agriculture ssistant, Sarawak), senior assistant agricultural fficer, Sarawak; D. W. A. Peters (laboratory techician, Medical Department, Somaliland Protectorate), aboratory superintendent, Virus Research Institute, igeria; A. McCallum, agricultural officer, Tanganyika; A. J. Ouseley-Smith, agricultural officer, Uganda; Dr. H. J. F. Cairns, medical research officer, grade 3, Virus Research Institute, Uganda; P. J. Byrne, veterinary officer, Tanganyika; R. F. Apps, scientific officer, Royal Observatory, Hong Kong; J. A. C. Davies, agricultural officer, Sierra Leone; H. S. Deans, assistant conservator of forests, Jamaica; R. Good, educational psychologist, Northern Rhodesia; J. G. Halcrow, entomologist, Colonial Insecticides Research Unit, Mauritius; R. C. Jones, hydrologist, Public Works Department, Kenya; R. M. Mabon, laboratory assistant, Veterinary Department, Tanganyika; Hon. P. L. A. O'Brien, geologist, Northern Rhodesia; Miss J. M. Slow, scientific officer, Maize and Produce Organization, Kenya; Dr. L. A. Whelan, soil chemist, Agricultural Department, Kenya.

The Behaviour of Bower-birds

DR. L. HARRISON MATTHEWS writes: "The article on 'The Behaviour of Bower-birds' that appeared in *Nature* of July 19, p. 110, is based on a review by Prof. Evelyn Hutchinson, of Yale University, that appeared in the *American Scientist* (40, No. 1). The writer of the article in *Nature* does not make it clear that this is a review by Prof. Hutchinson of original work published by Dr. A. J. Marshall at various times in *Nature* and the *Proceedings of the Zoological Society of London*. Prof. Hutchinson gives due credit to the author of the papers which he reviews, but it should also be made clear to readers of *Nature* that the original work was done, not by Prof. Hutchinson, but by Dr. Marshall".

The writer of the article did mention that it was based on Prof. Hutchinson's review; but we regret that no reference was made to the original work by Dr. A. J. Marshall.

Announcements

DR. H. A. B. SIMONS has been appointed to the readership in physics tenable at the Royal Free Hospital School of Medicine, London, from October 1.

THE United States Government and the Institute of International Education are offering grants or supplements to existing grants for graduate study in an American university during the year 1953–54. Applicants must be citizens of the United Kingdom or the British Colonies, less than thirty years old, and must possess a bachelor's degree or its equivalent. Application forms (to be completed by November 1) can be obtained from Mrs. D. R. Dalton, Universities Department, English-Speaking Union, 37 Charles Street, Berkeley Square, London, W.1. Applicants from the British Commonwealth, other than those in the above category, should apply to the respective United States embassy in their own country for information on similar grants.

ERRATUM.—Mr. W. D. Furneaux writes that in his communication to *Nature* of July 5, p. 37, entitled "Some Speed, Error and Difficulty Relationships within a Problem-solving Situation", he has inadvertently omitted a t from equations (1) and (2), which should therefore read as follows:

$$P_S = \int_0^t \frac{1}{\sigma_S t\sqrt{2\pi}} \exp - (\log t - mD + S)^2 / 2\sigma_S{}^2 dt \quad (1)$$

$$P_C = 1 - \int_0^t \frac{1}{\sigma_C t\sqrt{2\pi}} \exp (\log t - C)^2 / 2\sigma_C{}^2 dt \quad (2)$$

LABORATORIES FOR CEMENT RESEARCH

THE new research laboratories of the Associated Portland Cement Manufacturers, Ltd., at Stone, in Kent, were opened on July 11 by the Minister of Works, the Right Hon. D. McA. Eccles. These laboratories, together with general offices, form a pleasant building, and the architects, Messrs. Westwood, Sons and Harrison, are to be congratulated on the effect of modestly decorating a functional building with Tyrolean and coloured finishes and by the occasional use of Kentish rag-stone.

In these laboratories and offices, a large staff of well-qualified scientific men and technicians will work towards the improvement of the quality of cement, the cheapening of production, and the introduction of new products, in addition to dealing with specific problems which continually arise. Engineering research in connexion with cement-making plant will form an important part of the work, as well as fundamental research in the chemistry and physics of cement manufacture, and its behaviour in the making and curing of concrete and many allied materials. The development and improvement of methods of manufacturing burnt clay, sulphate-resisting and low-heat cement are also important objects.

The laboratories are well equipped. The lay-out of the chemical laboratories is of particular interest. Artificial ventilation effectively disposes of fumes, and subsidiary side-rooms are provided to house such equipment as muffles, furnaces, hot plates, water-baths and additional fume cupboards, etc. The Physical Testing Department has the usual equipment for cement and concrete testing, including temperature- and humidity-controlled curing rooms. It is evident from results that when testing is carried out under rigorously controlled conditions the uniformity of strength of cubes is as good as can be desired when made from the same batches of cement.

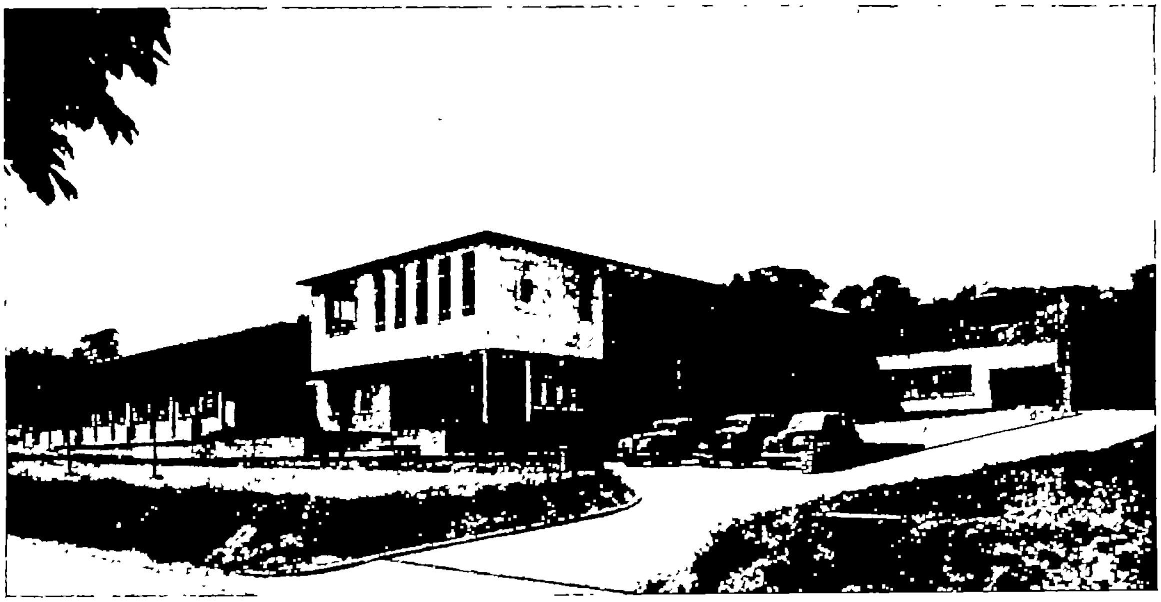

Fig. 1. Research Laboratories of the Associated Portland Cement Manufacturers, Ltd., at Stone

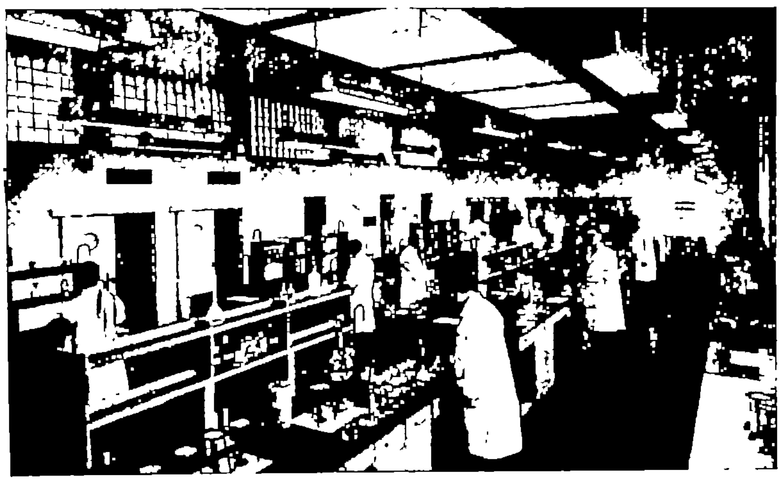

Fig. 2 Chemical Laboratories

It would take too much space to describe in detail all departments but it should be mentioned that in the laboratories there is a Kilns and Mills Division, and a Raw Materials Section, both well equipped and doing important work. There is a Microscopic Department, and a Library is beginning to accumulate. There is a lecture room in which instruction is given to personnel undergoing training in cement technology. This activity is considered to be one of the most important functions of the laboratory. A large and pleasant canteen has been rovided ; in fact, the visitor receives the impression hat every aspect of planning has been well conidered.

The staff of the laboratory will no doubt contribute greatly in the future towards improvements in the ement industry, and so give further help towards he solution of some of our economic problems, to which the cement industry has already contributed much.

GERMAN SOCIETY FOR ELECTRON MICROSCOPY

FOURTH ANNUAL CONFERENCE

THE fourth annual conference of the German Society for Electron Microscopy took place this year at Tubingen during June 6–9. The increasing interest evoked by this event, both inside and outside Germany, may be judged by the attendance at the conference of more than two hundred electron microscopists, many of whom came from abroad. Although this was not an international conference, eight European countries were, in fact, represented. A high standard was maintained both in the papers presented and in the discussions. It was felt, however, that the total number of eighty papers was rather large considering the limited time available. It is only possible to mention a few of the papers here, and these have been chosen so far as possible to indicate the general scope of the conference.

The chairman of the Society, Prof. U. Hofmann, delivered the opening lecture, choosing as his subject "The Electron-Microscope in the Treatment of Problems in Inorganic Chemistry". The electron microscope, he said, has made its contribution to organic chemistry largely by virtue of its ability to resolve fine structures, particularly those of crystals. It has been used, for example, for determining the structure of graphite crystals in connexion with problems of lubrication. Similarly, with its aid, progress has been made in the chemistry of soils and clays and in the selection of suitable fillers for rubbers. Although the resolving power of the electron microscope is not yet sufficient to resolve atomic structure, it is often possible to use the instrument for obtaining an estimate of surface area and crystal size, thus obtaining a valuable check on X-ray determinations from line-broadening measurements.

Several papers were devoted to the imaging properties of electron lenses. H. Bremmer developed a simple approximate formula for the axial field distribution in a magnetic lens in terms of the lens excitation and pole-piece geometry. S. Leisegang presented a theoretical paper on the form of the caustics arising in lenses suffering from astigmatism. Previous work by W. Glaser and E. Regenstreif was reviewed, and a number of caustic cross-sections were shown arising from different types of field asymmetry. By observing such caustics in a lens provided with a suitable correcting device, it is possible in principle to compensate the lens astigmatism.

F. Lenz and M. Hahn showed how this could be done experimentally. Electrons are arranged to travel through an astigmatic lens in slightly under-telescopic ray-paths. The emerging electrons strike a distant fluorescent screen forming a pattern there, consisting of an astroid surrounded by a circle. Using Sturrock's theory of the astigmatic lens, Lenz and Hahn have correlated quantitatively the dimensions of this pattern with the asymmetries of the pole-piece system. Experimental results were shown for a particular magnetic lens in which the astigmatic difference of foci goes through a minimum value as the lens excitation is increased from zero to the maximum value available.

B. Von Borries, F. Lenz and G. Opfer described some experimental work undertaken to resolve a discrepancy amounting to 10 per cent between the focal lengths of a magnetic objective lens as calculated by Lenz and those measured by E. Ruska. Ruska's measurements were repeated and found correct. Further experiments on the magnetic circuit showed that, due to the design of the iron casing of the lens and to the B/H properties of the iron used, a loss of magnetomotive force of 5 per cent occurred, causing an increase in focal length of 10 per cent above the calculated value. This accounted for the discrepancy.

R. Seeliger reported progress in the attempts to construct an electron microscope in which the primary spherical aberration is eliminated using correction methods proposed by Scherzer. The mechanical and electrical stability of the instrument has been considerably improved, and the complete correction of primary spherical aberration has been realized. There are, however, many practical difficulties still to be overcome in connexion with the stability of the specimen, etc., before the greatly increased theoretical resolving power of the lens system can be fully attained.

A new approach to the problem of reflexion specimens for the electron microscope was put forward by G. Mollenstedt and H. Duker. Measurements of the velocity distribution of secondary electrons leaving a surface which is subjected to ion bombardment showed that the energy spread was only 3 eV. In the new microscope a metal specimen is placed at right angles to the optical axis and is bombarded with low-voltage ions by means of an ion source mounted at an angle of 45° to the specimen. The resulting secondary electrons are imaged at the fluorescent screen by an electrostatic lens placed immediately below the specimen. An accelerating voltage of 30 kV. is employed. The image has the appearance of that due to a shadowed specimen owing to the inclination of the ion source, thus facilitating the interpretation of the pictures. The resolution is at present about 1000 A. ; but it is believed that this can be improved considerably. The defects associated with previous systems employing glancing incidence at the specimen, namely, gross distortion of the field and high chromatic aberration, are avoided.

L. Wegmann outlined the design of a new Trub-Täuber electron microscope which embodies several novel constructional features. An electrostatic objective and first projector lens are used, only the final projector being magnetic. The lenses are mounted on a hinged door provided with a vacuum seal. This construction makes the lenses readily accessible. In addition, the projector lenses are mounted on bearings so that they may be swung out of the path of the beam when a direct diffraction pattern is required. Two ranges of magnification are provided : 800–4,000 for comparison work with the optical microscope, and 8,000–14,000. A focusing aid is incorporated which causes three images of each object point to appear when the instrument is incorrectly focused. This is achieved by providing two extra-axial holes in the condenser aperture in addition to the normal central one. In ordinary use the illuminating beam passes through the central hole only; but, by switching in an A.C. deflexion system, the illuminating beam traverses the outer holes as well, giving rise to three images on the screen when the objective lens is defocused.

E. Kinder discussed the design of small microscopes. He gave his opinion that there is a place for a small microscope with a resolution of 100 A. and a magnification of 3,000. It should be provided with a transparent screen and pocket magnifier. The cost should be one-fifth of the price of an instrument having a resolution of 20 A.

The fluorescent screen received its share of attention. H. Arend, E. Ruska and I. Broser described quantitative measurements on the resolving power and light-conversion efficiency of a number of fluorescent screens. Their apparatus allows eight fluorescent screens to be viewed consecutively by either an optical microscope or a photomultiplier, without breaking the vacuum. A series of curves showed the effect of grain size and screen thickness on light output for both reflexion and transmission screens.

Dealing with the subject of electron diffraction, A. Boettcher and R. Thun described a dynamic electron diffraction apparatus in which phase changes in a specimen can be recorded on a single photographic plate. The instrument resembles the ordinary diffraction apparatus but is provided with a slit in front of the camera. This slit selects part of the ring diffraction pattern across a diameter. The specimen is heated up and the plate is traversed horizontally, thus producing a set of diffraction patterns corresponding to a given range of temperature. In this way, phase changes occurring in as short a time as fifteen seconds have been recorded. By using specially prepared alloy specimens, phase diagrams can also be obtained for simple alloy systems.

In connexion with the use of the electron diffraction camera, O. Radczewski outlined recent progress in interpreting the patterns obtained when investigating the structure of minerals.

Among many papers on the application of the electron microscope, only a few can be mentioned here. M. Fahnenbrock and W. Liese have investigated the mechanism of liquid flow control in the pores of certain conifers, using a 'Perspex' replica method with silicon monoxide shadowing. They have succeeded in building up a fairly complete picture of both the fine and gross structure of these pores which are several microns in overall size. These pores contain a central membrane carrying a central torus. In order to resolve the fine structure an electron microscope is needed. This paper was typical of many in which the higher resolving power of the electron microscope is used for building up a complete picture of comparatively large structures previously investigated with the optical microscope.

At the conference considerable importance was attached to the question of the falsification of object detail introduced by the preparation technique. E. Perner and G. Pfefferkorn described critical comparisons they had made on the effect of methods of specimen preparation for the electron microscope on plant chondriosomes. Micrograms obtained in the electron microscope were compared with those obtained directly using an optical phase-contrast microscope. Considerable differences in shape and structure were apparent. The authors concluded that this was due to the homogenizing and fixation technique, and were of the opinion that preparation methods which had proved successful for animal structure could not be applied to botanical material.

Of no less importance are the changes that occur in the specimen material due to the electron bombardment. A. Brookes, M. Knoch and H. König reported further measurements on the variations that occur when polystyrene latex and nitrocellulose are bombarded with electrons. It was stated that an electron 'dosage' of only 1×10^{-4} coulombs/cm.^{2} is sufficient for detectable changes to occur in nitrocellulose, 4×10^{-3} coulombs/cm.^{2} being the corresponding dosage for polystyrene latex. This corresponds roughly to only one or two electrons per square angstrom at the specimen.

L. Wegmann showed examples of specimen damage by comparing micrograms taken with object loadings of 2,000 and 10,000 W./cm.^{2} respectively. The use of beam-limiting apertures was suggested to limit the area of the specimen being irradiated.

It may be remarked here that the question of specimen contamination, that is, the formation of a visible deposit on the specimen at somewhat higher dosages, received very little attention in comparison with the variations that occur in organic material.

Several speakers dealt with the detection of defects which frequently occur in crystals. R. Bernard and E. Pernoux gave examples of the *Schlieren* effects that arise in the imaging of very thin crystals in the electron microscope. G. Möllenstedt, and also O. Rang, showed how the size and position of cavities and other defects in crystals can be determined by correlating a particular electron diffraction pattern quantitatively with the corresponding area of the specimen. This is done by selecting a particular ray from the diffraction pattern, by means of an aperture, and using it to form a focused image of the corresponding area of the specimen.

The advantages of stereoscopic methods were emphasized by R. Rühle and E. Zehender. The special object-holder employed in the Bosch electron microscope enables the operator to rotate the specimen through 25° without appreciable transverse object movement. In this way a good idea can be gained of the surface contour of the specimen before a photograph is taken. A short film was shown of the appearance of the image as the object is rotated.

J. Helmcke and B. Jahn demonstrated by means of stereoscopic projection the structure of the dentine canals in human teeth.

V. C. Dalitz and J. A. Schuchmann reported on their work in developing the 'carbon' skin replica method described at last year's conference by Konig. J. Helmcke had used a somewhat similar technique to investigate the fine structure in thick membrane films.

Other speakers dealt with the preparation of textural components in steels and the application of the point emission microscope to metallurgical problems. Papers were given on the investigation of colloidal fractions of the soil, methods of preparation of bacteriophage, and the examination of plant cells with the aid of the microtome.

Electron microscopy in the U.S.S.R. was reviewed by F. Lenz. He stated that most of our information is based on the proceedings of a conference on electron microscopy held in Moscow in 1950. There are more than a hundred Russian-built electron microscopes in the Soviet Union using magnetic lenses. The design follows closely that of the Siemens instrument. There are also a number of electrostatic instruments.

fost of these instruments are operated on behalf of he electrical industry. Research is being carried out n the imaging properties of electron lenses, and the roduction of high voltages using high-frequency scillators. Investigations are being pursued into the cattering properties of electrons and the interaction f electrons and the photographic plate.

An exhibition of photomicrographs was held llustrating the topics dealt with at the conference, nd interesting large-scale demonstrations of optical iffraction effects were given by Prof. Kossel.

T. MULVEY

PRIMITIVE MEDICINE AT THE WELLCOME HISTORICAL MUSEUM

ON July 18 the new exhibition at the Wellcome Historical Medical Museum, 28 Portman Square, ondon, W.1, which bears the title "The Medicine of he Aboriginal Peoples in the British Commonwealth", vas officially opened, and on that occasion Lord Vebb-Johnson delivered an address. In his intro-uctory remarks the director of the Museum, Dr. shworth Underwood, explained that the scope of he exhibition has been restricted to the primitive aces in the Commonwealth in order to enable the ubject to be covered in the limited space available; his arrangement nevertheless allows of a cross-ection of the world to be illustrated.

The exhibition is divided into a number of sections vhich lead from general primitive conceptions, hrough ideas regarding the nature of disease, to its reatment by non-rational and by rational methods. he sequence then follows the detailed methods used n treatment, and the practices which are employed r the protection of the individual, both against isease and danger in general, and also against specific ilments.

In the section dealing with general knowledge arious fine carvings, such as a genealogical stave, hould be mentioned. In the section dealing with the ause of disease, attention should be directed to the ne series of sago-pith effigies from Borneo, to the arious memorial heads, the finely carved soul-atchers, and to the unique exhibit illustrating the ult of the god of smallpox in the Yoruba mythology. he practice of the medicine man himself is well lustrated, and the very complete outfits actually sed by certain individual medicine-men will be of he greatest interest. This section contains a number f fine carvings, especially the spirit-masks and the ront-pieces of ceremonial head-dresses.

In the section dealing with treatment, attention hould be directed to the outfit actually used by the ersonal medicine man to Cetewayo, which contains number of horns used for cupping purposes. The arious instruments and operations shown in the ection on surgery illustrate the ingenuity of primitive eoples in making very simple instruments serve a pecific purpose. The practice of artificial deformation s illustrated by some most interesting specimens, ncluding a rare preserved head showing the practice f elaborate facial tattooing which, among the Maori, vas reserved for chiefs and other important persons.

The ritual background on which primitive medicine ests is shown by a number of most interesting arvings, some of which are used as masks in the eremonies of various secret societies. These exhibits cannot be easily described; but attention should be directed to the very fine carved elephant's tusk from Benin which epitomizes so much of the background of African ritual and legend.

All the exhibits in this exhibition are selected from the collections in the Museum. The exhibition deals with subjects which are little known, and the detailed catalogue includes the fruits of extensive research. The catalogue is published by the Oxford University Press* on behalf of the Museum.

SOUTH-WESTERN NATURALISTS' UNION

CONFERENCE AT PLYMOUTH

THE South-Western Naturalists' Union held its annual Whitsuntide conference during May 30–June 2 at Plymouth, at the invitation of the Plymouth and District Field Club and the Plymouth Institution. Some eighty members attended.

On May 30, the Mayor of Plymouth (Alderman H. Wright) received the delegates and members at the City Art Gallery. Afterwards Mr. H. G. Hussell showed a series of films illustrating the animal and plant life of the neighbourhood.

Most of Saturday, May 31, was taken up by a river excursion up the Tamar as far as Calstock. Mr. G. M. Spooner pointed out features of interest along the route; in the afternoon Cotehele House, formerly owned by the Earl of Edgecombe and now in the possession of the National Trust, was visited.

In the evening, Mr. Mervyn G. Palmer gave his presidential address; his subject was "Lundy". In his comprehensive survey of the island, he dealt with the geology, topography and history of Lundy and with its animal and plant life, paying particular attention to the birds.

A coach tour across the southern part of Dartmoor occupied most of June 1, and the hut circles at Grimspound and the stone avenue and menhirs at Merrivale were visited. Mr. Spooner again acted as leader.

The annual general meeting, following a meeting of the Council of the Association, was held on June 2. In his report, the honorary secretary, Dr. Stanley Smith, stated that at the present time the Union embraces twenty-two societies, one institution and one private member. A letter from the honorary secretary of the Ilfracombe Field Club inviting the South-Western Naturalists' Union to hold its next conference at Ilfracombe was then read, and the invitation accepted. Mr. Mervyn Palmer agreed to continue in office as president for another year, and the other officers were all re-elected: *Hon. Secretary*, Dr. Stanley Smith (University, Bristol, 8); *Hon. Assistant Secretary*, Miss Elizabeth Fleure; *Hon. Treasurer*, Mr. H. W. Turner; and *Hon. Auditor*, Dr. F. S. Wallis, Mr. G. M. Spooner, Mr. G. Tipper and Mr. O. G. Watkins were added to the Council.

On behalf of everyone present, Mr. Palmer thanked the Plymouth societies for their hospitality and all individual members of the Plymouth and District Field Club and Plymouth Institution who had contributed to the success of the conference. He particularly mentioned Mr. O. G. Watkins, who had carried out the duties of local secretary, and Mr. Spooner, who acted as leader in the field.

Members had the choice of one of three excursions on the afternoon of June 2: a visit to the Aquarium and Laboratory of the Marine Biological Association; Buckland Abbey; and Plympton Castle.

SOVIET FAMILY LEGISLATION

CONSIDERING the concept of the family in Soviet life Dr. R. A. J. Schlesinger suggests that the U.S.S.R. does not just represent an attempt at the application of socialist theories in a modern industrial society. In considering any matter in the U.S.S.R. it should be realized that it is not a country but a continent; at the time of the Bolshevik revolution Russia comprised a greater variety of civilizations than it does at present, after a systematic process of industrialization (*Health Educ. J.*, 10, No. 2; April 1952).

In some areas until quite recently millions of peasant homes in Russia were man-dominated in the most brutal sense of the term, and women's condition deteriorated, at least in the poor peasant's home when the economic differentiation in the village increased its dependence on the richer neighbour. Of the Islamic regions some—especially the Volga Tartars—were fairly advanced; but most of them (especially Central Asia) belonged to the most backward provinces of the Islamic world. There were large areas over which a primitive tribal organization was still in operation. As late as 1936 the Government struggle against blood-feud was just in its concluding stage. Large sections of the penal codes of the Republics concerned dealt with paying bride-price, abducting women, polygamy, marriage of minors and similar "offences originating from tribal custom", some of which (for example, marriage of minors) came under heavy penal sanctions only if they were caused by local custom which the legislator wished to repress in the interest of the emancipation of women.

Confronted with the initiation of a revolution in human relations against the prejudices of primitive custom, the Soviet state has firmly kept to the Marxist concept that undesirable phenomena in family life should, and can, be overcome by the removal of their economic causes. In 1935 Stalin hailed the Labour Day as the great emancipator of peasant women because it granted them an income independent of that of their menfolk. To-day the Soviet Government is attempting to construct a modern industrial society in which its policies aim at stabilizing family relationships in such a society.

Before this were possible, however, certain 'house-cleaning' had to be concluded. In the 'house-cleaning' programme the first enactments of the revolutionary Government did not exceed measures current in modern legislation elsewhere. They were revolutionary only in comparison with Tsarist Russian legislation and consisted of such measures as the transfer of marriage and divorce from the Church to the registrar's office, admission of divorce on the joint petition of both parties, or by court decision on the petition of only one party, the decision being left to the judge's discretion.

Much confusion about the real social situation has been created and is still being created by exaggerated emphasis on some literary pronouncements. Even in statements by authors who must be regarded as characteristic of the Soviet outlook, concepts of an eventual withering away of the family played a predominant part. The withering process, however always referred to the family as an economic unit o consumption and as the main place of education, and not as a normally permanent union of man and wife To some extent this may have been due to the impact of the more Utopian elements of Marxist ideology to some extent to exaggerated estimates of the potentialities of some measures which are clearly necessary in order to enable women to take their share in production, such as crèches, pre-schoo education and public canteens.

This view has now completely changed and, in al Soviet publications since 1936, the family is described with great fervour as "the primary unit of our Sovie society". The Ministry of Education publishes a special monthly, *Family and School*, to promote collaboration between home and school and the activities of parents' committees. Great emphasis i laid upon the responsibilities, not only of parents towards their children, but also of the younger members of the family towards the aged ones. The reasons for this change are political as well as economic.

After having passed its revolutionary period—which, *a posteriori*, is explained by the consideration that it was necessary in order to break up some millions of unfree relationships and to establish the principle of equality of the sexes—Soviet legislation as enacted in the period 1936–45, has come to conclusions very similar to those current in other advanced industrial countries. Most of the differences may be explained by the absence of traditional prejudice; the Soviet State can leave the decision upon whether a divorce should be granted or not to the judge's common sense, without binding him by enumerating grounds for divorce, the presence of which gives a claim to, and the absence of which excludes, granting of a divorce. It can also encourage marriage without paying tribute to the concept that being an unmarried mother is morally wrong.

In essence, however, the conclusions arrived at are the same: marriage is the normal way to motherhood; the family home is the ordinary, though not the only, place to rear the new generation; men and women have equal rights within the family as well as in professional life. The real problems of th Soviet approach to the family arise less from th consummation of the permanent results of th feminist movement than from the potential contradiction between the recognition of the family hom as one centre in the education of the future citizen and the demand for the access of women, not only in theory, but also in practice, to all professions for which they are physically fitted.

INHIBITION OF ŒSTRUS BY CULTIVATED GROMWELL

By DR. B. P. WIESNER and PROF. JOHN YUDKIN
Department of Physiology, King's College of Household and
Social Science (University of London)

IN one settlement of the Shoshone Indians, infusion of the roots of *Lithospermum ruderale*, Dougl. taken orally, were believed to have contraceptiv properties[1]. Prompted by this, Cranston[2] administered fluid extracts of the herb to mice in their food She observed inhibition of œstrus and fertility during treatment, without any evidence of general toxicity

Other workers confirmed these findings and also xtended them by showing, for example, an inhibition f certain mammary tumours[3,4]. We have observed a omplete inhibition of œstrus in mice of the *C3H* train by aqueous extracts of *Lithospermum ruderale* administered daily for four weeks.

Lithospermum ruderale is not readily available and batches of this plant vary greatly in activity. However, we have found that English gromwell (*L. fficinale* Linn.), which can be cultivated, yields œstrus-inhibiting extracts.

Cultivation. Seeds of wild gromwell were sown in February under glass, pricked off in 3-in. pots at the end of April, and planted out in May in open limed beds. Plants, including roots, were harvested in October.

Stabilization. We found that delay in processing or slow drying of wild plants tends to result in loss of activity. The cultivated plants were therefore dried at 60° C. immediately after harvesting. This procedure effected stabilization.

Preparation of extracts. The dried plants are finely ground and the powder is extracted with cold distilled water for 45 min. After filtration, the residue s re-extracted with water at 60° C. The second extract is cooled, combined with the first and freeze-dried, since there appears to be loss of activity in aqueous solutions even when they are stored in the cold.

Administration to mice. Tests were made on mature female mice of the *C3H* strain with high œstrous frequency, established by daily vaginal smears during a preliminary period of at least seven weeks. They received daily, by stomach tube, freshly made aqueous solutions of the freeze-dried extract. After preliminary experiments with herb-diet mixtures, this method of administration was adopted because of the uniformity of dosage and the avoidance of complicating factors such as reduced food-intake[4] and inactivation on standing. Smears were taken daily and showed that the equivalent of 1 gm. of the ground dried herb inhibited œstrus, cornification remaining in abeyance from the third day after beginning of treatment until four to five days after its cessation. There is, however, considerable variation in the dosage response; for example, reduction of the initial dose of 1 gm. to 0·5 gm. herb-equivalent daily may maintain inhibition of œstrus. No toxic or other side-effects were noted. After termination of treatment, the œstrus rhythm returned to normal within three days.

Administration to human subjects. Although gromwell has long been used as a medicament and for preparing a popular beverage, no ill-effects have been reported. The observations in mice also suggested that experiments in human subjects were permissible. Preliminary experiments were thus made with the small quantities of extracts available.

(*a*) Single doses of active aqueous extract corresponding to 10 gm. of dried herb per day evoked no subjective effects or obvious objective effects in three subjects (two women, one man).

(*b*) A nulliparous woman aged thirty-four consumed, from the first day to the seventh day of the menstrual cycle, freeze-dried extract, equivalent to about 20 gm. dry herb per day; from the eighth day of the cycle until menstruation the daily dose was doubled. Indices of ovarian function, both œstrogenic and luteal, were recorded before, during and after treatment. These included vaginal cell content, characteristics of cervical secretion, waking temperature and endometrial differentiation. There was no manifest change in the œstrogen response, but during treatment the ovulatory rise in the waking temperature was small compared with previous and subsequent records, and the progestational development of the endometrium was less than in the proceding and subsequent cycles. There were no other subjective or objective effects; for example, no changes in blood picture, urinary findings or pulse-rate. It would appear, therefore, that daily doses of roughly 20–40 mouse units did not inhibit œstrogenic secretion in the subject, but may have reduced the level of luteal secretion. The occurrence of luteinization is, of course, not incompatible with the suppression of ovulation. No risks of conception were taken by the subject during the treatment.

Our thanks are due to: Mr. W. W. Binns and Miss B. P. Jackson for pharmacognostic advice and preparation of extracts; Mr. John Gilmour and Mr. F. Hanger for collecting and cultivating *Lithospermum officinale*; Messrs. Ayerst, McKenna and Harrison, Ltd., for supplying extract of *L. ruderale*; Mr. E. C. Moran for presenting dried *L. ruderale*; Dr. Mary Barton for collecting specimens from the experimental subjects; Dr. E. N. Brand for carrying out bacteriological and other examinations; Mrs. E. N. Blacker and Miss Mary Jewell for technical assistance. The cost of these investigations was borne in part by a grant from Messrs. Kylon, Ltd. [March 25.

REVERSAL OF THE MOLECULAR SET IN KERATIN

By J. SIKORSKI

Textile Physics Laboratory, Department of Textile Industries, University of Leeds

THE stability of α-type proteins is due to the combined effect of hydrogen bonds and cystine cross-linkages. Thus proteins with a low cystine content, for example, myosin, are very labile under conditions favouring heat denaturation[1]; they show supercontraction in hot water, and their crystallites are transformed into the β-configuration; but this crystallographic transformation can be reversed simply by treatment in saturated urea solution[2].

Having a much higher cystine content, animal hairs are, under similar conditions, extremely stable. Even prolonged treatment in water at 90° C. (for example, for periods up to twelve days) is ineffective in producing supercontraction. Such treatments may, indeed, lead to the appearance in the X-ray photograph of the first traces of the equatorial reflexion of spacing 4·65 A.; but concurrently there is a loss of cystine sulphur[3]. In order to produce supercontraction in the presence of water alone, it is necessary to resort to high-pressure steam[4] (in which case hydrolysis of the main chain occurs) or to make use of the results of stress relaxation in stretched fibres[5].

Stability in hot water is not an exclusive property of the α-form; it is also induced in the β-form, when extended fibres (the crystallites of which are in the β-configuration) are exposed to the action of steam; this effect is generally recognized as being the cause of the 'setting' properties of keratin fibres[4].

A study of the stability of steam-set β-keratin is thus of considerable importance. In particular, a demonstration of the possibility of reversal of set β-keratin to the original α-configuration would serve two purposes: (1) from the character of the reagents capable of producing the effect it might be possible to assess the importance of the various types of molecular interaction which have been suggested as being responsible for the stability of set β-keratin; and (2) a study of the reconstituted α-keratin might throw further light on the problem of the long-range elasticity of keratin fibres.

With reference to the first point, Rudall has shown that saturated urea solutions at room temperature can reconvert set β-crystallites to the α-form, if the time of setting is restricted to a few minutes[2]. He concluded that hydrogen bonds must be responsible for the setting properties of keratin. I have obtained similar results when I treated fibres, which had been set in boiling water under tension for five minutes, in 0·15 *N* sodium hydroxide or 75 per cent lithium bromide solutions at room temperature, but only partial reconversion in 98–100 per cent formic acid. In all these reagents the degree of reversal was decreased when the time of setting was increased, and with fibres set for five hours no effect whatsoever was observed in saturated urea and only a partial effect in the other reagents. These results lend strong support to Speakman's conclusion[7], based on experiments in which the contraction of set fibres in various reagents is compared with that of normal fibres, that dimensional set is due in part to linkages other than hydrogen bonds.

Since the above reagents, chosen because of their probable effect on hydrogen bonds, are, in the main, ineffective in eliminating completely the set in the crystallites of keratin, efforts were made to find other reagents which would have the desired action. The only one which I have found to be effective is cuprammonium hydroxide. When fibres which had been set in boiling water at 50 per cent extension were immersed in solutions of this reagent, and afterwards in dilute sulphuric acid in order to remove the absorbed copper, they were left in a condition such that the X-ray photograph showed only the α-form whatever the time of the initial setting. Similar reconversion was observed in fibres set in steam at 100 per cent extension, and in fibres which had supercontracted after treatment in steam at high pressure. The degree of reconversion in such experiments depends on the time of treatment in the cuprammonium hydroxide solution, and for complete reversal to the α-form it is essential that the fibres should absorb enough copper to ensure the disappearance of the X-ray photograph[8].

Fibres in which the crystalline set had been eliminated in the way described still showed the normal reversible α ⇌ β transformation on stretching and release in water, although higher extensions than usual were necessary to produce the complete transformation. The fibres could also be set again in boiling water; the set β-crystallites were again stable except in cuprammonium hydroxide, which caused a complete reconversion to the α-configuration as before. In fact, the cycle, α → set β → α, could be gone through repeatedly with the same fibres. In all these respects the fibres behaved very much like normal fibres; but that there had nevertheless been a considerable change in the properties was shown by their behaviour when exposed without constraint to the action of water at high temperatures, for such treatment produced the supercontraction and spontaneous appearance of the β-form which is, as mentioned above, characteristic of the more labile proteins. Since normal fibres are not affected in this way by the action of cuprammonium hydroxide and sulphuric acid, the linkages—or some of them—responsible for the stability of the α-form must be broken during the relaxation of tension in water at high temperatures. We may also conclude that, if the setting phenomenon is due in part to reformation of cross-linkages, their effect is not powerful enough to produce stability in cuprammonium hydroxide solution. The action of cuprammonium hydroxide solution may be either to reduce the number of such reformed linkages, a possibility which is unlikely on chemical grounds[9], or to induce refolding by a co-ordination mechanism similar to that proposed by Whewell and Woods[8] to account for the supercontraction of unstrained virgin wool fibres in cuprammonium hydroxide solutions. Even then, however, we must postulate that some of the linkages responsible for the set have actually been eliminated by the cuprammonium hydroxide, for the fibres do not revert to the β-configuration after removal of copper.

I wish to thank Mr. H. J. Woods for his advice, and Prof. J. B. Speakman and Dr. C. S. Whewell for the benefit of many discussions; I am also indebted to the International Wool Secretariat for grants in aid of these investigations. [Feb. 7.

CARBOHYDRATIC FERMENTATION OF BACTERIAL ISOLATES FROM ZYGOPHYLLACEOUS AND LEGUMINOUS ROOT-NODULES

By Prof. M. A. MOSTAFA
Fouad I University, Cairo

So far, the previous work done on zygophyllaceous root nodules[1,2] has dealt with the following problems: (*a*) effect of soil sterilization on growth response of *Zygophyllum coccineum* and on its nodular formation; (*b*) the capacities of zygophyllaceous bacterial isolates to produce nodules in some members of Leguminosae; (*c*) the growth response and stimulation of nodular formation in *Zygophyllum coccineum* either to its own specific bacterial isolate or to those isolated from *Tribulus alatus* and *Fagonia arabica*. In the present work, attempts have been made to elucidate the physiological identities of some zygophyllaceous and leguminous bacterial isolates in ms of their fermentation potentialities on various rbohydratic sources. Two zygophyllaceous nodular cterial strains, namely, those isolated from *Zygo-yllum coccineum* and *Tribulus alatus*, are compared th a *Rhizobium* strain isolated from root nodules a leguminous plant (that is, *Arachis hypogæa*).

The medium used was that suggested by Baldwin d Fred[3], with the variation of the carbon source follows: (1) *monosaccharides:* xylose, glucose, vulose and D-galactose, and (2) *disaccharides:* crose, maltose and lactose. Since some sugars were und to break down during autoclaving, the medium for each experimental carbon source—is divided to two portions: one portion was sterilized by toclaving, and the other was cold-sterilized by enon's technique[4]. The latter involves the trans-rence of the medium into an ice chest and left r twenty-four hours, heated for ten minutes at ° C., and then returned back again to the ice est; the whole process was repeated three con-cutive times.

For expressing the bacterial fermentation poten-alities, the following criteria have been determined:) relative growth; (2) pH variation; (3) gas oduction.

Comparisons of fermentation characteristics of rious monosaccharides, as induced by different cterial isolates from zygophyllaceous and legum-ous root nodules, have been made after six weeks cubation. In both xylose and glucose, incubation as carried out at 37° C., while it was at 32° C. in vulose and D-galactose. Concerning the relative owths of the three bacterial isolates, as influenced the nature of the experimental monosaccharide, ose from *Zygophyllum coccineum* and *Arachis pogæa* show that xylose is the most favourable, llowed by glucose and levulose, while D-galactose the least favourable. Except in D-galactose, on hich both *Zygophyllum* and *Arachis* bacterial olates show a very slight growth, *Arachis rhizobium* rain shows—on the whole—a comparatively more gorous growth than that of *Zygophyllum* on the her experimental monosaccharides. On the other nd, glucose is the most favourable for *Tribulus* cterial isolate, followed by levulose, while both lose and D-galactose are the least favourable. The ree bacterial isolates tend to lower the pH value both xylose and glucose; it does not change preciably, however, on either levulose or D-galactose. ey differ with regard to gas production; the sults can be summarized as follows.

(1) The *Arachis rhizobium* strain does not produce y gas. In a similar manner, Fred, Baldwin and cCory[5] stated that the evolution of gas in liquid ltures of *Rhizobia* is not rapid enough to form gas bbles.

(2) Except on autoclaved glucose medium, where ere is gas production, *Zygophyllum* bacterial olate behaves in a similar manner to *Rhizobia* in e non-production of gas.

(3) *Tribulus* bacterial isolate differs, however, in at gas production takes place on both autoclaved vulose and D-galactose media. The restriction of s-production to autoclaved monosaccharide media ay be due to the effect of hydrolysis during auto-aving, which enables the bacterial isolate to initiate fermentative potentiality.

In a similar manner, comparisons have been made on different disaccharides—after six weeks incubation at 20° C. A study of the relative growths of the three bacterial isolates shows that the most favourable one is maltose. *Tribulus* bacterial isolate continues to grow equally well, to some extent, on both lactose and glucose media. On the other hand, *Arachis* strain differs from that of *Tribulus* in exhibiting a very slight growth on different treatments of either lactose or sucrose media. Similarly, *Zygophyllum* strain shows a very slight growth on autoclaved lactose and sucrose media; its growth becomes, however, comparatively greater on the two latter disaccharides when the media are cold-sterilized by Menon's technique instead of being autoclaved. Except on lactose medium, the three bacterial isolates are found to be acid producers; they tend to lower the pH value. This tendency is comparatively greater with *Arachis* strain on both sucrose and maltose media. The fermentative potentiality, as expressed by gas production, is a constant and prominent feature of *Tribulus* bacterial isolate on the differently treated experimental disaccharide media. On the other hand, both *Zygophyllum* and *Arachis* strains agree in their feeble fermentative potentialities; gas production can only be detected either when *Zygophyllum* bacterial strain grows on cold-sterilized lactose or when that of *Arachis* grows on autoclaved maltose.

Thus, according to fermentation characteristics on different monosaccharides and disaccharides, the three bacterial isolates can roughly fall into two categories: one category includes the two bacterial isolates from root nodules of *Zygophyllum coccineum* and *Arachis hypogæa*, and the other contains only *Tribulus* bacterial strain which stands rather physiologically distinct. The similarity of *Zygophyllum* and *Arachis* bacterial isolates manifests itself in the following behaviours: (1) the most favourable monosaccharide for growth is xylose, followed by glucose and levulose, while the least favourable is D-galactose; (2) the feeble or non-production of gas on most monosaccharide and disaccharide media; (3) the most favourable disaccharide for growth is maltose, while there is a very slight growth on autoclaved lactose and sucrose media. *Tribulus* bacterial isolate differs, however, with regard to its relative growth on different monosaccharide and disaccharide media and with regard to its fermentative potentialities. It produces gas on all differently treated disaccharide media, as well as on two autoclaved monosaccharide media (namely, levulose and D-galactose).

This work indicates that the two zygophyllaceous bacterial strains, namely, those isolated from root nodules of *Zygophyllum coccineum* and *Tribulus alatus*, are physiologically distinct in respect to their relative growths and to their fermentation potentialities. *Zygophyllum coccineum* bacterial isolate behaves even more similarly to leguminous *Arachis rhizobium* strain than to that of its zygophyllaceous colleague isolated from *Tribulus alatus*. Further work on the fermentation potentialities of the three bacterial nodular isolates, on different polysaccharides and nitrogen sources, are still in progress.

I wish to express my gratitude to Mr. Z. Mahmoud for his continual assistance. [June 12.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Stereochemistry of the Tropane Alkaloids

THE respective C$_3$-configurations of the epimeric N-acyl-nortropins have been recently established from the different behaviour of the epimers[1] in acyl migration, N → O. Naturally occurring psi-tropine derivatives seem on this basis to contain a hydroxyl group *syn*-placed to the ring-nitrogen. Atropine, hyoscyamine, convolamine, being hydrolysable to tropine or nortropine, appear, therefore, to represent *anti*-3-tropanol structures.

These investigations have now been extended to ecgonine (I *b*) and psi-ecgonine (II *b*), and to two cocaine-epimers.

Ecgonine and psi-ecgonine are C$_2$-epimers[2]. In alkaline medium ecgonine is converted[3] into psi-ecgonine, in analogy to the tropine (*anti*-tropanol) → psi-(*syn*)-tropine conversion, which indicates identical C$_3$-configuration for tropine and ecgonine, and the respective epimeric configurations for the corresponding ψ-derivatives.

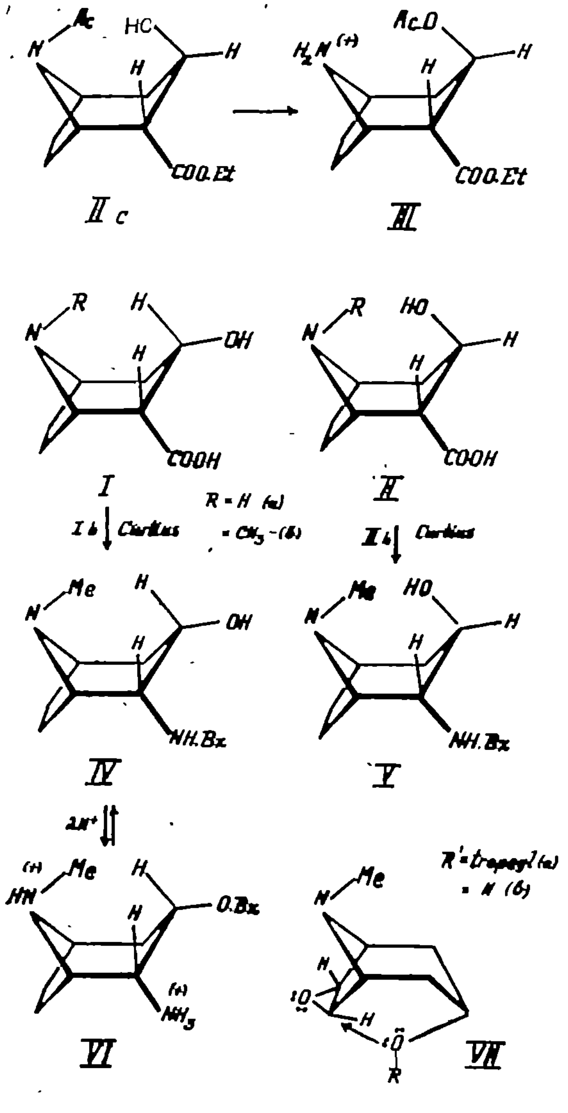
This inference has now been confirmed experimentally. Hydrogen chloride in dioxane converts N-acetyl-nor-ψ-ecgonine ethyl-ester (m.p. 112°) (II *c*) to O-acetyl-nor-ψ-ecgonine ethyl-ester hydrochloride (m.p. 226°; $[\alpha]_D = +23 \cdot 6°$) (III), while under strictly identical conditions no amino ester was obtained from the epimeric nor-ecgonine derivative (II *a*). In ψ-nor-ecgonine and its derivatives, the C$_3$-hydroxyl seems, therefore, to be *syn*-placed to the nitrogen, the opposite following for nor-ecgonine and cocaine.

These results did not permit any statement to be made on the position of the C$_2$-carboxylic group of the *syn* and *anti* ecgonine epimers with respect to the C$_3$-hydroxyl. No generally applicable methods being available for the determination of the configuration of beta-hydroxy-carboxylic acids[4], an attempt was made to overcome this difficulty by converting the two ecgonine C$_2$-epimers to the corresponding 2-amino-tropanol-3-epimers and subsequent comparison of the respective N-benzoyl derivatives (IV and V). In this conversion the migrating group would—just as in the Curtius reaction—be assumed to retain its configuration[5], which then makes it possible to determine the steric position of the amino-group in respect to the carboxylic group and, by inference, the configuration of the carboxyl in the original ecgonine epimers.

2-Benzamido-3-*anti*-tropanol (m.p. 163°, $[\alpha]_D = -6°$; IV), prepared from *anti*-ecgonine, was converted by absolute ethanolic hydrogen chloride quantitatively into 2-amino-3-*anti*-benzoyloxy-tropane *bis*-hydrochloride (m.p. 214–216°; $[\alpha]_D = -22°$; VI). Under identical conditions, 2-benzamido-*syn*-3-tropanol (V; m.p. 205°) affords only the monohydrochloride of (V), that is, in the latter case no acyl migration N → O is taking place. Thus the amino and hydroxyl groups are shown to be *cis* in the 2-amino-*anti*-tropanol, and *trans* in the *syn*-tropanol epimer. Obviously, in ecgonine and in cocaine the carboxylic and C$_3$-hydroxyl groups occupy the same corresponding positions. Hence, cocaine is (−) 2-*cis*-carbomethoxy 3-*anti*-benzoyloxy-tropane. As another approach t the problem, the two ecgoninol C$_3$-epimers were pre pared by reduction of the methyl esters of (I) an (II) with lithium aluminium hydride, which conver sion leaves the asymmetrical carbon atoms intac These epimers will be compared in other stereo specific reactions at some later date.

These results admit the following interpretation c previous findings of earlier authors. It is well known[3] that (I *b*) is more readily converted into anhydrc ecgonine than (II *b*). This dehydration appears t involve a *trans*-elimination[7], and is evidence that, i ecgonine, C$_2$—H and C$_3$—OH are *trans* (polar, polar[8]) situated. It follows, then, that in (*anti*)-ecgonine th relative positions of the carboxyl and hydroxyl ar *cis*, the reverse being true for *syn*-(ψ)-ecgonine, whic is in complete agreement with the results of th above acyl migration experiments.

It is intended to investigate the configuration o the "third racemate"[2] of ecgonine and that of the ye unknown fourth epimer by the same methods. Th third racemate cannot be epimerized, and, bein readily dehydratable, appears to have C$_3$—OH an C$_2$—H in the *trans* configuration (polar, polar). There



re, the C_3—OH would be predicted to be *sym* placed respect of the nitrogen. For the fourth racemate, erefore, the structure of a 2-*trans*-carboxy-3-*anti*-opanol seems to be valid.

Our experiments also point to the fact that opolamine and scopine (VII *a* and *b*) can only be rivatives of tropine (*anti*-3-tropanol), as they are adily converted[9,10] into the tetrahydrofurane deriva-ve scopoline. The rupture of the epoxide ring of opolamine can only be attributed to the rearward icleophilic attack of the C_6-oxygen. Accordingly, e *trans* position of the epoxide ring of scopolamine, well as that of the C_6-hydroxyl group of scopoline relation to the C_3-oxygen, appears to be likewise oved. It is intended to establish these predictions experimental investigation of the existing con-gurative correlations between scopolamine, valeroi-ne and tropine.

Experimental details will be submitted to the *urnal of the Chemical Society*.

Note (*March* 28).—Ecgoninol can be converted in e presence of benzenesulphonic acid to the cyclic nzylidene acetal, whereas ψ-ecgoninol remains ichanged under the same conditions.

Ecgonine (I) and ψ-ecgonine (II) fail to form loralids, (I) undergoing dehydration to anhydro-gonine and (II) remaining unchanged.

These findings support the configuration ascribed oove to the ecgonine epimers.

Use of *n*-Butanol – Formic Acid – Water Mixture in the Paper Chromatography of Amino-Acids and Sugars

DURING the course of a systematic investigation of ne amino-acids of the sugar cane, it became desirable o record simultaneously the amino-acid distribution n material from several sources. Two-dimensional hromatograms developed by Consden, Gordon and lartin[1], although effecting excellent resolution of the onstituents of a mixture, suffer from the disadvantage hat only one sample can be mapped at a time. loreover, the application of controls necessitates the reparation of separate maps. On the other hand, he single-dimensional 'strip chromatogram' offers a nuch more rapid method of analysing mixtures of mino-acids; but the use of phenol-aqueous mmonia as solvent was found to give rather poor eparation of individual amino-acids. Under tropical conditions, darkening of the solvent was an added difficulty.

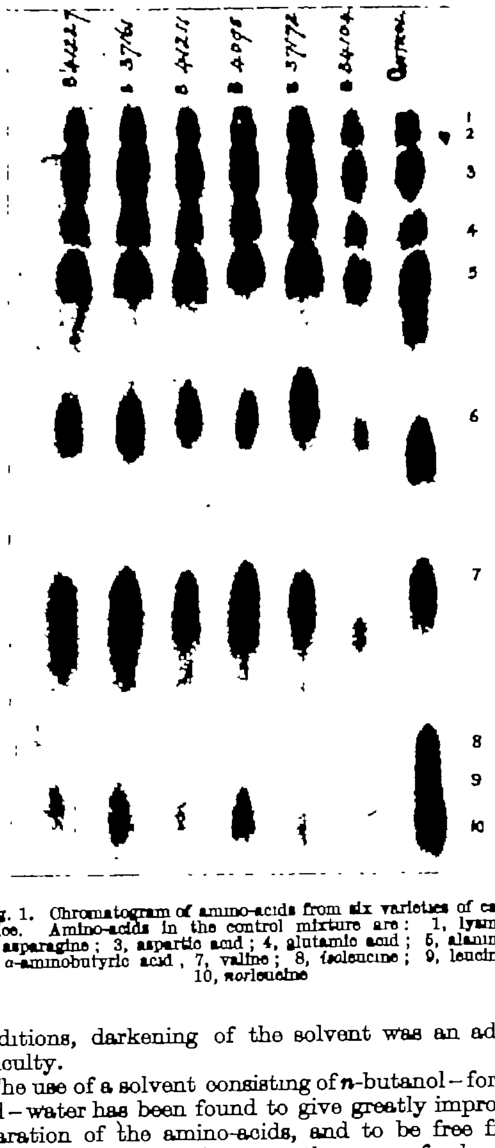

Fig. 1. Chromatogram of amino-acids from six varieties of cane juice. Amino-acids in the control mixture are: 1, lysine, 2, asparagine; 3, aspartic acid; 4, glutamic acid; 5, alanine, 6, α-aminobutyric acid, 7, valine; 8, *iso*leucine; 9, leucine; 10, *nor*leucine

The use of a solvent consisting of *n*-butanol – formic acid – water has been found to give greatly improved separation of the amino-acids, and to be free from the numerous objections to the use of phenolic solvents. The solvent was prepared by refluxing for an hour a mixture of formic acid (90 per cent, 50 c.c.), *n*-butanol (600 c.c.) and water (50 c.c.). A further 300 c.c. of water was then added and the mixture shaken from time to time during cooling. After being kept for twenty-four hours, the upper solvent layer was separated and was then ready for use.

Fig. 1 is a photograph of a typical chromatogram obtained for the amino-acids of the juice of six varieties of mature sugar cane. These cane varieties, all derived from the Cane Breeding Station in Barbados, were grown in Trinidad concurrently and were harvested at the same time. The amino-acids were obtained from the fresh juice by adsorption on columns of 'Amberlite IR 120', followed by washing with water and elution with dilute ammonia. After concentration *in vacuo*, the extracts were chromatographed on Whatman No. 1 filter paper in the usual manner for forty hours in the above solvent. The chromatograms were developed by spraying with ninhydrin (0·4 per cent) and cobalt chloride (0·2 per cent) in *iso*propyl alcohol, and heating at 110° C. for ten minutes. The amino-acids showed up as

Fig. 2. Chromatogram of a sugar mixture in formic acid-n-butanol-water solvent. The sugars shown are: 1, raffinose; 2, sucrose; 3, glucose; 4, fructose; 5, xylose; 6, rhamnose

salmon-coloured spots rapidly turning bright magenta red.

The six varieties of sugar cane examined all show a very similar amino-acid pattern, as can be seen from the photograph, which also indicates the identity of the individual spots shown on the chromatogram. An interesting point is that, in the solvent used, asparagine has a smaller R_F value than aspartic acid (the sequence of amino-acids in the control mixture was previously determined by running them separately), whereas in phenol the reverse is true. Similarly, lysine, which has a large R_F value in phenol, has a very small R_F value in the solvent here described.

A full account of the qualitative and quantitative examination of the amino-acids of sugar cane will be published elsewhere.

The solvent described above can also be used satisfactorily for the chromatographic separation of sugars. Fig. 2 is a photograph of a chromatogram obtained in a 40-hr. run from a mixture of glucose, fructose, sucrose, xylose, rhamnose and raffinose, after development of the chromatogram with aniline phosphate in butanol, a reagent which, as found by Bryson and Mitchell[2], showed up all the sugars satisfactorily.

Plasma Thromboplastin

WHEN whole normal blood clots in a glass tube, the generation of thrombin can be observed by removing 0·1-ml. amounts at intervals and adding these to fibrinogen. The clotting times of the fibrinogen samples will record the amount of thrombin present. When this is done, it is found that there is a phase lasting 3–4 min. in which no thrombin can be detected. Thereafter an extremely rapid formation of thrombin occurs, and all the prothrombin is converted to thrombin in 2 or 3 min. This separation of thrombin formation into two phases suggests that there is a powerful intrinsic thromboplastic activity of blood, but that 3–4 min. are required for its formation.

The plasma of a patient deficient in prothrombin but apparently lacking in no other factors was useful for the demonstration of plasma thromboplastin activity. A 1/5 dilution of the patient's plasma was mixed with washed platelets from normal plasma and calcium chloride. At intervals samples were remove from this incubation mixture and added to norm plasma made platelet-deficient by centrifuging, an the mixtures were immediately recalcified. Th clotting times of the normal plasma mixtures ar shown in Table 1. In this experiment the clottin of the substrate plasma samples certainly cannot b attributed to thrombin transferred from the incubation mixture because very little thrombin was formed The potency of this thromboplastin requires littl emphasis. A 1/5 dilution of plasma mixed wit platelets formed a thromboplastin comparable i strength to undiluted brain emulsions.

Table 1. FORMATION OF THROMBOPLASTIN IN PROTHROMBIN-DEFICIEN PLASMA

0·3 ml. of 1/5 plasma was mixed with 0·3 ml. platelet suspensio (318,000 per c.mm.) and 0·3 ml. of *M*/40 $CaCl_2$. At intervals 0·1 m of this incubation mixture was added to 0·1 ml. of normal plasm and the mixture immediately recalcified with 0·1 ml. of *M*/40 CaC The clotting times are recorded in seconds. The fibrinogen clotti times give an indication of the amounts of thrombin transferred fro the incubation mixture.

Incubation mixture	Substrate	Time intervals in minutes for withdrawal of samples from the incubation mixture								
		½	1	2	3	4	6	8	16	32
Equal parts of: (1) Prothrombin-deficient plasma 1/5	Recalcified normal plasma	37	24	18	16	16	15	15	17	21
(2) Platelets (3) *M*/40 $CaCl_2$	Fibrinogen	660	163	300	460	570	960	1,800+		

The factors required for the formation of thromboplastin are platelets, the 'antihæmophilic globulin and factor VII[1]. Factor VII is probably identica with serum prothrombin conversion accelerator[2] convertin[3], and co-thromboplastin[4]. The formation o this thromboplastin in the factors isolated fron normal plasma and serum is shown in Table 2.

Table 2. FORMATION OF THROMBOPLASTIN FROM FACTORS ISOLATE FROM NORMAL PLASMA AND SERUM

'Antihæmophilic globulin'. The fraction precipitated by 33 per cen saturation with $(NH_4)_2SO_4$ from normal plasma previously treate with $Al(OH)_3$ to remove prothrombin.

Factor VII. The fraction of serum prepared by $Al(OH)_3$ adsorptio and subsequent elution with phosphate buffer at pH 8.

Platelets: 700,000 c.mm. prepared from normal plasma.

0·2 ml. amounts of antihæmophilic globulin, factor VII, platele and *M*/40 $CaCl_2$ were mixed, and at intervals 0·1 ml. of the incubatio mixture was added to 0·1 ml. of normal plasma and the mixtu immediately recalcified with 0·1 ml of *M*/40 $CaCl_2$.

The clotting times were recorded in seconds.

Incubation mixture	Substrate	Time intervals in minutes for the withdrawal of samples from the incubation mixture					
		1	2	4	8	16	32
Equal parts of 'antihæmophilic globulin', factor VII, platelets, *M*/40 $CaCl_2$	Recalcified normal plasma	53	51	25	18	13	14

It appears that platelets are the main quantitativ precursor of thromboplastin, and that the anti hæmophilic globulin and factor VII are required i relatively small amounts. This work will be reporte in detail elsewhere.

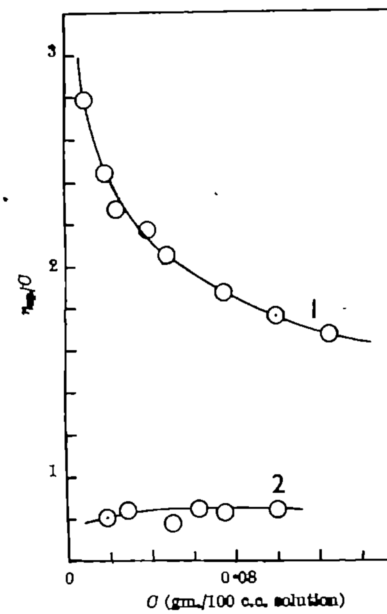
Viscosity of Sodium Salt of Polyuronide Hemicellulose from Jute

IT has been observed by Fuoss and Strauss[1] that e viscosity behaviour of a polymer such as poly- ylbutyl pyridonium bromide, containing ionizable oups, in water is not the same as that of a neutral lymer. The reduced viscosity (η_{sp}/C) of the former polyelectrolyte), unlike that of a neutral polymer, creases on dilution. A similar behaviour has been ted by Pals and Hermans[2] in the case of sodium otinate. Basu[3] has studied the viscosity of sodium ymonucleate, which also behaves as a polyelectro- te. The present communication describes the scosity measurements of the sodium salt of methyl- onic acid – xylan complex[4] (a jute hemicellulose ction). As this uronic acid is believed to occur in chain molecule, it was thought that the sodium lt of the complex in aqueous solution might also have as a polyelectrolyte. This does not appear have been studied hitherto.

The results of viscosity determinations are shown aphically ; curve 1 shows that the reduced viscosity tually increases on dilution. In the presence of 1 *N* sodium chloride solution, the sodium salt behaves a neutral polymer. These facts may be readily ex- ained by the conception of polyelectrolytes put rward by Fuoss and Strauss[1]. Viscosities were easured in an Ostwald viscometer with an efflux time r water of about 165 sec. at 32° C.



Reduced viscosity of (1) sodium salt of methyluronic acid – xylan complex, (2) same in presence of sodium chloride

Defatted jute was delignified with 'Textone'[5] ; the r-dry holocellulose thus obtained was treated with ·3 per cent caustic soda solution (w/w) at room mperature for two hours and filtered through a ntered-glass filter. The filtrate was acidified with lacial acetic acid, and an equal volume of absolute thyl alcohol was then added. The precipitate was ltered off and washed free from acetate with queous ethyl alcohol (1 : 1). The sodium salt of emicellulose (acetic acid is too weak to decompose) thus obtained was purified by dissolving in per cent caustic soda solution at room temperature, filtering and washing the precipitate first with aqueous ethyl alcohol (50 per cent) and then with absolute alcohol. This was dried in a vacuum desiccator over concentrated sulphuric acid.

My thanks are due to Dr. P. B. Sarkar, director of the Technological Research Laboratories, Indian Central Jute Committee, for his interest in this work.

Biological Activity of some Enteramine-related Substances

THE action of enteramine on various biological test objects has been established in previous investigations[1].

The present communication represents a preliminary contribution to the comparative study of the actions developed, on some of the most important and significant biological reactives of enteramine, by a number of enteramine-related indole derivatives.

The results obtained with indol- and hydroxyindolalkylamines on the diuresis of hydrated rats (antidiuretic action), on the blood pressure of the spinal cat (hypertensive action), as well as on the isolated oestrus-uterus of the rat, and the *in situ* urinary bladder of the dog (stimulant action), are summarized in the accompanying table.

The activity of enteramine is arbitrarily taken as 100 ; the activity of the other substances is expressed in percentage.

	Hydrated rats' diuresis	Rat oestrus-uterus	Dog urinary bladder	Spinal cat blood pressure
Enteramine	100	100	100	100
Bufotenine	6–7	10	5–10	50
Bufotenidine	<0·3	0	?	400–600
Bufothionine	0	0	0	0
Dehydrobufotenine	0	0	0	0
Tryptamine	0·3–0·5	1–1·5	1·5	12–16
1-Methyltryptamine	0·1–0·2	1–3	1–1·5	10–12
N-Methyltryptamine	<0·3	<0·5	<0·5	10
N,N-Dimethyltryptamine	<0·3	<0·5	<0·5	6–8
5-Methoxytryptamine	25–40	25–30	30–35	30–50
Adrenaline	diuretic action	inhibition	inhibition	2,000–3,000

The following compounds have proved wholly inactive on all the above biological reactives : indole, skatole, 5-methoxyindole, β-(indole-3)-acetic acid, β-(indole-3)-propionic acid, γ-(indole-3)-*n*-butyric acid, tryptophane, tryptophanol, hypophorine.

From the data in the table and from the study of numerous records, the following conclusions may be drawn.

(*a*) Among the indolalkylamines hitherto tested, enteramine possesses the most powerful action on the diuresis and the uterus of the rat, and on the urinary bladder of the dog. Moreover, the biological reactives are in no way damaged by the substance, as shown by the easily repeatable pharmacological response, and, when working with isolated organs, by the prompt reversibility of this response, however intense it may be, after washing out.

This by no means occurs with bufotenine or with the methyltryptamines, which, on the contrary, may greatly damage the smooth muscle.

(*b*) 5-Methoxytryptamine is the product which most closely approaches to enteramine, both qualitatively and quantitatively; bufotenine (= N,N-dimethylenteramine) does it to a much lesser degree.

It seems, therefore, that for the appearance of the specific antidiuretic and uterus-stimulating actions the peculiar structure of the lateral chain of enteramine (chain with two carbon atoms, with a primary amino-group attached to the terminal carbon atom) is as important as the presence of a free phenolic hydroxy group in position 5.

(*c*) A satisfactory agreement exists between the antidiuretic action of the different substances and their uterus- and bladder-stimulating action. No relationship exists, on the contrary, between the antidiuretic action and the hypertensive action in the spinal cat.

I wish to thank Prof. R. H. Manske for the methyltryptamines.

A Bacterial Growth-Factor Synthesized by a Soil Bacterium

Earlier studies in this laboratory[1] have indicated the presence in soil of bacteria dependent upon growth-factors provided by soil extract but not by yeast extract nor by combinations of amino-acids and vitamins (not including B_{12}). More recently it was shown[2,3] that for many of the indigenous soil bacteria dependent upon essential growth-factors supplied by soil extract, the nutrilite effect of the latter could be replaced by vitamin B_{12}. Other micro-organisms, however, remained dependent upon unidentified growth-promoting substances in soil.

In a study of the growth requirements of certain bacterial strains for the nutrition of which vitamin B_{12} was unable to replace soil extract, it was found that a number of bacteria isolated from soil and having simple nutritional needs were able to synthesize a factor nutritionally equivalent to soil extract. Using a selected test organism requiring the growth-factor (No. 88) and one capable of synthesizing it (No. *B*89), both pleomorphic bacteria of the 'soil diphtheroid' type and apparently undescribed species, more detailed study was made. With a basal medium of inorganic salts, sugar and yeast extract ('Difco'), the test organism gave no response to the addition of any of the following: thiamine, riboflavin, niacin, pyridoxin, pyridoxal, pyridoxamine, pantothenic acid, biotin, folic acid, vitamin B_{12}, *p*-aminobenzoic acid, inositol, choline, combinations of B vitamins, cytosine, thymine, uracil, adenine, guanine, xanthine, cystine, β-alanine, ribonucleic acid, desoxyribonucleic acid, oleic acid, tomato juice filtrate, casamino-acids, enzymatic casein digest and soil extract ash. On the other hand, growth resulted from additions of small amounts of the culture filtrate of organism No. *B*89, grown in a simple nutrient medium containing only inorganic salts and sugar (see accompanying table). Partially purified material from the metabolic liquid gave observable growth response at approximate 0·1 p.p.m. concentration.

Growth Response of Organism No. 88 (Washed Cells)

Addenda to basal medium*	Optical density (aver. of 4 tests)
None	0·005
Soil extract	0·132

* Salts, glucose and yeast extract.

It was further found that a growth-factor effe equivalent to that given by filtrate *B*89 was obtaine on addition of injectable "15 unit" liver extract. Th effect was not attributable to vitamin B_{12} as indicate in the table, showing results with different amoun of liver extract and equivalent concentrations c crystalline vitamin B_{12}. Growth stimulation c *Lactobacillus leichmannii* by a factor in liver extra which promotes growth in excess of that attributab to vitamin B_{12} has been reported[4], while concentrat from liver have been found[5] to contain a factor r quired by *Leuconostoc citrovorum* which appears t be identical with 'folinic acid'[6]. Since these facto were reported to be present in yeast or yeast extrac there is reason for assuming that the factor produce by organism *B*89 is a different substance. Th latter is believed to represent a nutrilite require for the growth of a group of indigenous soil bacter and to contribute to the growth-promoting properti of soil extract. It is considered a matter of intere that it is nutritionally equivalent (for the te bacterium) to a factor in liver extract and that is a product of microbial synthesis.

Inhibitors of Hyaluronidase

An unsolved problem in the study of rheumat diseases is whether or not hyaluronidase plays an part in the typical changes in the connective tissu particularly of the interfibrillar cement substanc which is believed to contain hyaluronic acid. Guerra for example, claimed that sodium salicylate si nificantly inhibits the spreading power of hya uronidase injected into the skin, and therefo ascribed the value of salicylate in rheumatic fever t an action of the drug on the hyaluronidase–hyaluron id system of the body. Meyer[2] and Dorfman *et al.*[3] nfirmed these observations, but gave no experi-ental data. Later, Meyer and Ragan[4] argued that e effect claimed by Guerra was due not to the sali-late but to gentisate, a supposed metabolic product salicylate. Further research has since shown that erapeutic concentrations of salicylate[5,6] or gent-ate[7] are too weak to inhibit hyaluronidase *in vitro*. oreover, Swyer[6], Dalgaard-Mikkelsen[8] and Jones[9] iled to find any demonstrable effect of salicylate i the spreading activity of hyaluronidase injected to the rabbit's skin. The evidence is thus contra-ctory and too weak to ascribe the value of salicylate rheumatic fever to an inhibition of hyaluronidase.

In an endeavour to clear up this problem, an vestigation was started at this laboratory in 1948. ne purposes of the investigation were to find potent, n-toxic inhibitors of hyaluronidase, and to ascer-in: (*a*) whether any such inhibitors are capable influencing the course of pathological changes in e ground substance of mesenchymal tissue; and) whether they are of value in the prophylactic or erapeutic treatment of diseases secondary to in-ctions with bacteria producing hyaluronidase, aluronidase being known to increase the permeabil-y of the tissue and thereby presumably to favour e invasion of the tissues by other micro-organisms.

Numerous organic compounds were tested viscosi-etrically for hyaluronidase-inhibiting properties. ighly purified testis hyaluronidase was mixed with e substance to be tested. Thirty minutes later the ixture was added to a 0·2 per cent solution of hyal-ronic acid from umbilical cord, which was adjusted a *p*H of 7 by means of phosphate. Readings were ken at 37° C. after different intervals. The investiga-on will be reported in detail elsewhere[10]. Certain lycondensation products built up of substituted iphenylmethane units proved powerful inhibitors of stis hyaluronidase. These compounds were obtained y allowing dihydroxy- or trihydroxy-benzoic acids react with formaldehyde under conditions favour-g the formation of condensation products of fairly gh molecular weight. Substitution in the methylene roups of these compounds by monohydroxy- or olyhydroxy-carboxyphenyl radicals produced still ronger inhibitors. These compounds were syn-esized by oxidizing polycondensed diphenylmethane erivatives with nitrous acid in the presence of suit-ble phenol derivatives. The inhibitory activity i *vitro* of some polycondensed diphenyl- and tri-henyl-methane derivatives and the acute oral oxicity of the compounds in mice are summarized i the accompanying table, which, for purposes of comparison, includes also corresponding values for salicylic acid and gentisic acid.

Compound		Inhibitory action on hyaluronidase (relative units · resorcinol = 1)	Acute oral toxicity (LD_{50} in mgm./100 gm.)
Polycondensed methylenedigentisic acid	7*P*	2,000	1,000
Polycondensed methylenedi-γ-resorcylic acid	24	1,850	400
Polycondensed hexahydroxytricarboxytriphenylmethane ('trigentisic acid')	21*P*	2,485	> 1,500
Polycondensed heptahydroxytricarboxytriphenylmethane ('di-β-resorcylic-gallic acid')	16*P*	1 300	540
Polycondensed heptahydroxytricarboxytriphenylmethane ('digentisic-gallic acid')	30	2,275	1,250
Salicylic acid		0·2	100
Gentisic acid		0 8	300

Of the diphenylmethane derivatives, it was a high-molecular weight condensation product of methylene-digentisic acid that showed the highest *in vitro* activity. The inhibitory activity of the triphenyl-methane derivatives synthesized by the reaction of polycondensed digentisic acid with gentisic acid or gallic acid was even stronger. The toxicity of the diphenylmethane and triphenylmethane derivatives tested is low (see accompanying table). The strong inhibitory action of these compounds was confirmed by experiments *in vivo*.

Reports[11,12] of these *in vivo* experiments and of clinical trials with the new inhibitors will be published in due course.

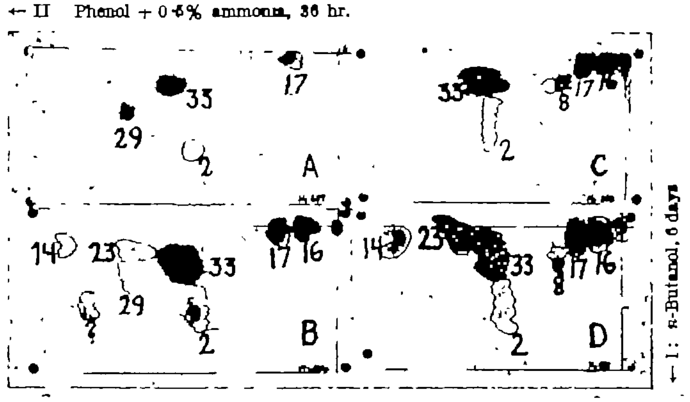
Free Amino-Acids in the Leaves, Roots and Root Nodules of the Alder (*Alnus*)

AN intensive fixation of atmospheric nitrogen takes place not only in the root nodules of leguminous plants but also in those of the alder[1]. For example, in a quartz sand culture of *Alnus glutinosa* with no combined nitrogen the growth was 261 cm. in length and the increase of nitrogen in the plant about 6·5 gm. in the second year (Virtanen and Saubert-v. Hausen). In order to gain information on the mechanism of the atmospheric nitrogen fixation and the nitrogen metabolism in general we have examined the seasonal occurrence of free amino-acids in the different parts of *A. glutinosa* and *A. incana*.

The free amino-acids were extracted by aqueous ethanol (70 per cent by weight) and the extracts were examined by two-dimensional paper chromatography (Fig. 1). Quantitative determinations were made by visual comparisons with a known series of dilutions. This method gives an accuracy of about 20–30 per cent. The method was controlled in respect to citrulline photometrically by diacetyl monoxime reaction[2].

The free amino-acid found most abundantly in the roots and nodules of the alder is L(+)-citrulline. In this respect alder differs distinctly from the leguminous plants, for example, *Pisum* and soya bean, in the roots and nodules of which asparagine and glutamine are found in abundance, but no citrulline[3,4]. Asparagine and glutamine are not found in the roots nor in the nodules of alder. The citrulline content of the nodules of both *Alnus* spp. increases greatly in the



Paper chromatograms of alcoholic (70 per cent by wt.) extracts from alder roots and nodules. Paper: Whatman No. 1, development by ninhydrin. *A*, nodules of *A. incana*, *B*, nodules of *A. glutinosa*, *C*, unnodulated roots of *A. glutinosa*; *D*, nodulated roots of *A. glutinosa*. 2 = alanine, 8 = serine, 14 = arginine, 16 = aspartic acid, 17 = glutamic acid, 23 = ornithine, 29 = γ-amino-butyric acid, 33 = citrulline

autumn, rising from about 0·2–0·3 per cent in the summer time to about 1–2 per cent of the dry weight of the tissue.

To confirm the identity of citrulline, it was isolated from the nodules of *A. incana* as the difficultly soluble copper salt, m.p. 266–268° C., which was in every respect identical with the authentic Cu-L(+)-citrullinate. The yield was 0·6 per cent of the dry weight. The nodules were harvested in October.

The nodules of *A. incana* (samples taken from Nature in August and October) contain, in addition to citrulline, appreciable quantities of γ-amino-butyric acid (*c.* 0·2 per cent of dry weight) with smaller amounts of alanine and glutamic acid but no other free amino-acids (Fig. 1,*A*).

The nodules of *A. glutinosa* (from laboratory cultures in January and May) differ from those of *A. incana* mainly by containing only traces of γ-amino-butyric acid (Fig. 1,*B*). In addition, they contain some aspartic acid and small amounts of arginine and ornithine. The roots of *A. glutinosa* (from laboratory culture in January) differ from the nodules taken from the same plant by containing somewhat less citrulline but much more arginine and ornithine (*c.* 0·1–0·2 per cent of dry weight) (Fig. 1,*D*). Those parts of the roots which are nearest to the nodules possess considerably higher concentrations of free amino-acids than do the more remote parts, but there is no qualitative difference. The leaves of *A. glutinosa* differed from the roots and nodules of the same plant mainly by containing less citrulline.

To ascertain whether the occurrence of citrulline in the nodules of the alder is possibly due to nitrogen-fixation taking place in the nodules or to nitrogen-metabolism, the free amino-acids of unnodulated alder roots were also examined. These alders were grown in sand and water cultures with combined nitrogen: nitrate, ammonium, aspartic acid–nitrogen. It was found that such roots, too, contain citrulline (Fig. 1,*C*), although considerably less than the nodulated roots (*c.* 0·1 per cent in winter). The presence of citrulline in the roots of alder is thus no consequence of the fixation of molecular nitrogen.

Other two-dimensional paper chromatograms were sprayed by *p*-dimethylamino-benzaldehyde reagent[5], which reacts with urea and ureides on paper, giving yellow spots. Intense citrulline spots were obtained from all the root and nodule extracts; but a detectable amount of urea was present only in the extract from the unnodulated roots (less than 0·0 per cent of dry weight).

So far as we know, citrulline has not bee found in the higher plants except in wate melon (*Citrullus vulgaris*), from which it wa originally isolated by Wada in 1930[6]. I is probably produced in alder roots by th Krebs–Henseleit cycle[7] from ornithine as i the animal organism, although there is n direct proof of this so far. It is noteworth that in winter the concentration of fre arginine and ornithine is high in the root near to the nodules but not in the nodule Borsook and Dubnoff[8] have shown tha citrulline reacts with glutamic or asparti acid while it is converted to arginine.

The great accumulation of citrulline i the nodules in the autumn suggests tha citrulline in the alder may have the role c a nitrogen store similar to that envisage for glutamine and asparagine in the legum inous plants.

A detailed description of this work will be publishe later.

A New Method for Isolating Members of the Acrasieæ from Soil Samples

METHODS for isolating members of the Acrasieæ which are slime moulds producing pseudoplasmodi and inhabiting soil, have been reported by variou workers[1–3]. The usual procedure is to inoculat directly on special media soil crumbs or soil/wate suspensions from samples being tested. The bacteri from the soil develop colonies which in turn becom the food source for the feeding myxamœbæ of th slime moulds.

The objection to these methods is that the fruitin phase of the Acrasieæ is often sparse and also over grown by various mould members of the fungi. Thi latter objection is true in part even on the nutrien 'lean' soil agar[4], which does delimit the growth of th unwanted forms. For these reasons a means wa sought of isolating members of the Acrasieæ whic would make it less difficult and cumbersome to sub culture the organism into 'pure-mixed' cultures[5] o *Escherichia coli*.

The new technique described here is simpler t operate and is more efficient. It tests larger quan tities of soil and still eliminates the contaminatin growth of other fungi almost completely. It als gives a view of the organisms under investigation mor nearly as they would appear *in vivo* in soil. The ne approach consists simply in first smear-inoculatin nutrient agar plates with *Escherichia coli*, ensuring heavy growth. Then with a sterile inoculating wir e growth is skimmed off the agar surface after -hr. incubation and suspended in sterile water.

The soil samples to be tested were previously pre- ared and placed in 25-c.c. specimen bottles. These ere sprinkled liberally with the bacteria in water ispension, enough to moisten the soil, not inundating . I find the 25-c.c. specimen bottles used by many f the biological supply houses are more than adequate r this purpose. The soil samples were loosely ulverized before being placed in the sterile 25-c.c. r to the level of one-half full. The loose-fitting etal cover completes the incubating chamber, which allowed to stand at room temperatures varying ithin limits of 20° to 23° C. After two days, pseudo- asmodia are visible, and after three days numerous uiting bodies will appear if the organisms were iginally present in the soil samples.

It is interesting to note that perhaps the appear- ice of the fruiting bodies on these cultures is more ke what it must appear to be in Nature, inasmuch they are on their natural substrate.

Escherichia coli was used as the bacterial food supply, nce past reports, and also my own experience, show at it is most suitable. Also this bacterium makes excellent food source for the Acrasieæ in 'pure- ixed' culture. Sub-culturing from the isolation als is a simple step of transferring a sorus to agar ntaining a 24-hr. old streak of *Escherichia coli*.

Nerve Impulses Originating from the Compound Eye of the Locust

ELECTRICAL changes in response to illumination of e insect eye have been studied previously[1]. These ve been related mainly to relatively slow potential riations, of the nature of retinal potentials, recorded om the eye itself. In addition, impulses in the rcum-œsophageal commissures of *Locusta migratoria* rrelated with changes of illumination have been ported[2].

We have found that similar or identical impulses, hich are of large amplitude and rapid conduction, ay be detected in the ventral nerve cord of the sect, as far caudally as the last thoracic ganglion, it not farther. The impulse discharges, which were ways in the form of short bursts, were found to be lated to two types of stimulus: (*a*) switching the ht on and off (constant illumination gave no dis- arge); (*b*) movement of an illuminated object the field of vision. The 'on' and 'off' discharges em to correspond with the 'on' and 'off' responses hich occur in vertebrate eyes, with the distinction at in our experiments these responses were detected the central nervous system of the insect, at some stance from the eyes. The responses to movement,), may be simply related to (*a*), in that a shift of umination from one ommatidium to another may be expected to give rise to an 'off' response, immediately followed by, or merging into, the succeeding 'on'. Hence single rapid movements of small extent are accompanied by single bursts of impulses. On this supposition, therefore, the smallest detectable shift of a light/dark boundary in the visual field would be referable to an angular movement corresponding to the angle subtended between the axes of two adjacent ommatidia, or a lesser angle.

Our experimental results have so far supported this view. With the insect firmly secured, the ventral nerve cord was exposed and placed on the recording electrodes. Responses to movement of a small light source in the visual field of one eye were studied. It was soon found that the response to any particular movement could only be elicited repeatedly if a sufficient interval were allowed between successive tests; the preparation became refractory to further stimulation for a period of 5–10 sec. after the first movement was made. Afterwards, test movements were made at 10-sec. intervals, and we report only on movements in a vertical plane.

It was found that consistent responses to movement were obtained until the angular movement of the source, referred to the eye of the insect, was reduced to approximately 1°. For smaller angles, responses were obtained in less than 100 per cent of trials, and for very small angles there was no response at all. Thus the minimum angular movement which gave 100 per cent responses was approximately 1°, which agrees very closely with the angular separation of the ommatidia of the eye measured by independent means.

These results are similar to those found for perception of vertical stripes by *Carausius*[3], and for moving stripes in the honey bee[4] and *Drosophila*[5]. An acuity of perception of movement by the insect eye of the same order as the ommatidial separation thus seems well established. The responses we obtained to smaller movements (down to ¼° in some cases) are difficult to explain, if we regard the ommatidium as a single functional unit. We are at present investigating these minimal responses on the assumption that they occur when the light source is moved just across the projected boundary between two ommatidia.

The preparation as a whole offers a ready means of studying a number of visual responses, for example, spectral sensitivity of the eye, reactions to changes of light intensity, extent of visual field and variations in response of different regions of the compound eye.

We think that the biological significance of the impulse discharges described lies in relation to the jumping habit of the insect, the impulses giving an effector response in the muscle of the jumping legs (last thoracic segment). We could find no similar responses in *Carausius*.

Heterozygosity, Environmental Variation and Heterosis

When a wild strain of *Drosophila melanogaster* is inbred under optimum conditions, the phenotypic variance of body-size is reduced by not much more than 50 per cent[1]. This suggests that nearly half the variance of the original strain was due to the effects of uncontrollable environmental variations within the culture. But highly inbred lines tend to have a much higher variance than crosses between them, so that the environmental variance in such quantitative characters is not constant for all genotypes and tends to be smaller in heterozygotes than homozygotes. This is illustrated in Table 1 for six highly inbred lines and the crosses between them. The lines came from two unrelated wild stocks, Nettlebed and Edinburgh, and include two lines selected for long wings (*LN* and *LE*), two selected for short wings (*SN* and *SE*) and two unselected lines (*UN* and *UE*). Wing-length is closely correlated with body-size, and variance is expressed as squared coefficient of variation, since this measure eliminates most of the effect of differences in absolute size.

Table 1. Phenotypic Variance of Inbred Lines and Crosses. Variance of wing-length in squared coefficients of variation

Strains crossed	Parental average	F_1	
LN × *SN*	1·79	1·37	females only
LE × *SE*	1·44	0·52	males only
UN × *UE*	2·27	1·11	sexes combined
SN × *UN*	2·85	1·88	,,
SE × *UE*	1·78	0·55	,,
SN × *SE*	4·00	2·00	,,
Average	2·35	1·24	

The inbred lines have, on the average, almost double the phenotypic variance of the crosses between them, and the same tendency is shown by crosses involving large, small and unselected lines. There are probably also differences in variance between the different inbred lines; but part of the differences between the parental averages for the six comparisons must be attributed to environmental differences between the experiments in which they were tested.

The relation between heterozygosity and environmental variance has been further analysed by preparing genotypes containing specific combinations of the three major chromosomes from inbred lines *SE* and *UE*, using methods which will be described elsewhere. If these genotypes are grouped according to the numbers of heterozygous pairs of chromosomes they carry, we find that the average variance of wing-length declines progressively with increase of heterozygosity (Table 2), so that the environmental variance of a particular genotype appears to be intimately related to the degree of heterozygosity.

A partial analysis of the *SN* × *UN* cross by the same technique shows the same general trend for size, and in view of the differences in variance between inbred lines and their crosses, it is likely to be a general phenomenon. The same general relationship also appears to hold for rate of egg production, both in comparisons between inbred lines and their crosses and in comparisons between the specific genotypes of differing heterozygosity referred to above. But problems of scaling make interpretation of these figures difficult, since the heterozygotes tend to have a much greater output than homozygotes. It seems probable that many quantitative characters in different animals and plants will show the same tendency for environmental variability, under given conditions to decrease as heterozygosity increases. It is not to be expected, of course, that the same rule would hold good when one is dealing with individual genes with large effects.

Table 2. Variance and Heterozygosity in *SE*/*UE* Genotypes

No. of major chromosome pairs heterozygous	No. of genotypes tested	Average variance of wing-length
Females		
0	5	2·54
1	9	2·23
2	5	1·44
3	1	1·20
Males		
0	5	1·64
1	7	1·31
2	2	1·19

Size in *Drosophila* shows the same phenomena of decline under inbreeding and heterosis in crosses between inbred lines as other quantitative characters. This suggests that heterosis, or increased size, vigour, etc., and reduced susceptibility to environmental variations are both manifestations of the same phenomenon of heterozygosity. There may be a general explanation for this relationship: the more heterozygous individuals will carry a greater diversity of alleles, and these are likely to endow them with a greater biochemical versatility in development. This will lead to heterosis, because of the more efficient use of the materials available in the environment, and also to a reduced sensitivity to environmental variations, since there will be more ways of overcoming the obstacles which such variations put in the way of normal development.

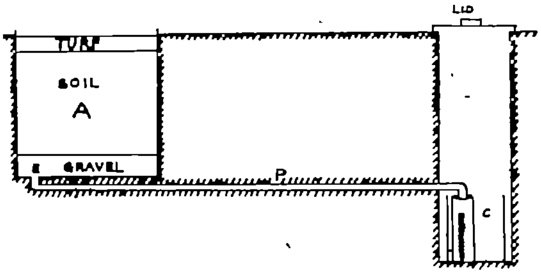
A Simple Apparatus for Measuring Potential Evapotranspiration

The combined process of evaporation from the soi and transpiration from plants is known as 'evapotranspiration'. The amount of moisture so used varies from place to place and depends mainly on climate (especially temperature and precipitation and the closeness of the vegetative cover. 'Potentia evapotranspiration', on the other hand, refers to th amount of moisture which would be utilized if supplie were unlimited and vegetative cover complete. It value, therefore, alters irrespective of precipitation and vegetation and is a function mainly of length of day and temperature[1].

Potential evapotranspiration can be measured simply and cheaply by an apparatus (see diagram made of oil drums, some lead piping and a suitably graduated jar. A 44-gallon drum (*A*) is cut down to a height of about 55 cm. From this a right-angled elbow (*E*) is led to a piece of ½-in. lead piping (*F* which drains into a container (*C*), where there is a graduated jar into which the overflow drip directly. There should be a protective shaft for thi container, which must be covered to stop the rain getting in.



A layer of gravel is put at the bottom of the apotranspirometer' (A) and the outlet (E) is ered by a small-meshed copper screen. Soil of a ht, friable nature, which permits free drainage and ter circulation, is placed in the tank (A) where, for eral purposes, grass should be grown. A suitable cedure is to install the apparatus in a level field grass so that the sod removed during installation n be replaced in the tank after the soil there has d time to settle. The area immediately surrounding apparatus should be kept well watered so that micro-climate above the tank and its surroundgs is as nearly similar as possible.

I installed an apparatus of this type in July 1951 the Johns Hopkins Laboratory of Climatology, abrook, New Jersey. It measures potential evapoanspiration by a very simple process. A known ount of water is applied to tank (A) and the ainage is collected in the overflow (C). Potential apotranspiration thus equals the amount of water plied plus precipitation, less the amount collected the overflow. The amount of water applied to the k and collected in the overflow can be converted sily to inches or millimetres of 'precipitation' as quired. This principle is the same as that used for more elaborate installations already at Seabrook, ainst which the new apparatus has been tested th satisfactory results. It can be read like a rainuge and, if erected at existing climate stations in ferent parts of the world, would add very little expense or observational time, since only one read- a day is required. In this way it could be used many areas to provide an indication of a climatic tor well worth more attention.

A New Serological Division of *Staphylococcus aureus* Bacteriophages: Group *G*

THE bacteriophages lysing *Staphylococcus aureus* ve been divided by Rountree[1] into five serological oups, designated A, B, C, D and F. Phages of oups A, B and F were isolated from lysogenic phylococci from human sources.

Three phages have been received in this Laboratory at are not neutralized by anti-sera of any of untree's groups. Each of these three phages is utralized by an anti-serum prepared against one the three, and this anti-serum fails to neutralize phages of the groups A–F. We refer to this new serological group as Group G.

The three phages are numbered 65, 66 and 68 in our collection. The first two were isolated by Dr. Wallmark of Stockholm using the cross-culture technique of Fisk[2], and are referred to as 155 and 166 by him[3]. The third phage, known as 68, was received from Dr. Wahl of Paris, and had appeared as a variant of one of the phages, $44A$, used for the routine typing of staphylococci[4].

Like the phages of groups A, B and F, these three phages lyse only coagulase-positive staphylococci; but they differ from these groups in lysing a greater variety of strains. Undiluted filtrates of all three lyse most coagulase-positive staphylococci; at their routine test dilutions the phages lyse about 40 per cent of a mixed group of strains, including strains of all the three major groups defined in routine phage typing and some strains not lysed by any of the typing phages. Because of the number of strains lysed, the group G phages are not used for phage-typing in this laboratory.

The plaque-size of these phages is often variable on a single culture; small clear, or indistinct, plaques may be mixed with larger plaques that are often surrounded by a halo. When picked and plated the phages giving these different plaques do not generally breed true.

Phages of group G may be readily propagated to high titre on nutrient agar, or in broth. In this respect, and in their wide lytic range, they resemble the phages of serological group D.

Nupserha bicolor Thoms., subsp. *postbrunnea* Breun.: a New Pest on Jute (*Corchorus olitorius* Linn.)

DAS[1] recently compiled a list of insect and mite pests of the two cultivated species of jute, namely, *Corchorus capsularis* and *Corchorus olitorius*. A pest, hitherto unrecorded in India, was detected in *olitorius* jute during 1949 on the farm of the Jute Agricultural Research Institute, and was identified by the Commonwealth Institute of Entomology, London, as *Nupserha bicolor* Thoms., subsp. *postbrunnea* Breun. The pest has since been found to be an important one for all the varieties of *C. olitorius*, while the *capsularis* varieties show resistance to it.

The pest has special economic importance, as it causes an immediate loss of a considerable portion of the stem. The ovipositing female cuts two rings around the stem with its sharp mandibles at two different levels, 0·7–2·7 cm. apart, with highest frequency between 1·0–1·4 cm. A slit is cut between the rings down to the pith tissue for oviposition. This causes withering and ultimate death of the apical plant region above the lower ring.

From our observations, it is presumed that the seat of oviposition chosen has a direct relation to the ratio of the length of mandibles of the laying female and the diameter of the stem. No oviposition has been recorded in stems outside the diameter range of 0·2–0·4 cm.; rings may be cut on stems of diameter up to 0·5 cm., but these do not generally exceed 0·4 per cent of the total. This clearly indicates the role of mandibles in the selection of diameter of stem for oviposition, and consequent susceptibility to damage.

Loss of plant height is therefore regulated by the actual seat of oviposition in the stem within the range of susceptible diameter. Frequencies of occurrence of height classes lost with susceptible diameter classes at the level of the lower ring show that the highest frequency lies in the height range 10–20 cm. and stem diameter 0·26–0·3 cm.

With susceptibility restricted to the apical part of the stem, loss of fibres becomes insignificant with older crops. It has been estimated that, in the young crop, loss of stem may be up to 30·02 per cent; in older crops, it is 6·32 per cent on the average.

Pre-ovipositing operations and feeding on the veins of the leaves by the adults, leaving the softer tissues intact, produce symptoms so specific that they may be taken as a field key for identification.

Crotalaria juncea, *C. saltiana*, *Hibiscus cannabinus*, *Aeschynomene aspera* and *Sesbania aegyptiaca* have been recorded as alternative host plants.

Fuller details will be published later. Thanks are due to Dr. B. C. Kundu, director of the Institute, for his helpful suggestions.

Bacterial Invasion

Let it be assumed that: (*a*) each organism invading a host has a chance λ of reaching a favourable site, and of afterwards undergoing a sequence of events which enable it to proliferate and result in the death (or infection) of the host; (*b*) each organism acts independently; (*c*) c inhaled organisms are necessary to produce the death (or infection) of 0·5 of the total of exposed animals; (*d*) the experimental animal population is large and homogeneous. Then the proportion S of animals remaining uninfected after the intake of n organisms each is given by:

$$S = (1 - \lambda)^n,$$

and by definition $0\cdot5 = (1 - \lambda)^c$.

Expressing n in units of c, that is, $n = fc$,

$$S = (1 - \lambda)^{fc} = 0\cdot5^f.$$

Where invasion by pathogens is through the respiratory system, these conditions might well apply. The argument is not invalidated by consideration of the case of many organisms grouped in one particle, since once the particle is deposited on a moist surface the cluster usually disintegrates and each organism has an independent subsequent history.

For the purpose of comparison with existing data on experimental respiratory infection available to me, the curve $S = 0\cdot5^f$ was plotted on the conventional probit–log dose plane. The curve shows a slight upward concavity, but is almost straight between the ED$_{25}$ and ED$_{75}$ values, having a mean slope approximately 1·9. Tables 1 and 2 show expe mental values of slopes for comparison.

Table 1. Slopes Obtained by Exposure of Animals to Clouds
Anthrax Spores (Ref. 1)

Animal	Size of particle inhaled	Slope ± 2σ range
Guinea pig	Single spore	1·26–2·13–3·0
,,	3·5 μ	1·31–2·44–3·57
,,	4·5 μ	0·59–1·26–1·93
,,	8 μ	1·67–2·54–3·41
,,	12 μ	0·72–1·25–1·78
Monkey	Single spore	1·45–3·19–4·93
,,	12 μ	0·32–1·17–2·02

Table 2. Slopes Obtained by Exposure of Guinea Pigs to Clo
of Single Organisms of the *Brucella* Group (Ref. 2)

Organism	Slope ± 2σ range
Br. suis	0·26–1·17–2·08
,,	1·64–2·86–4·08
,,	1·47–2·61–3·75
,,	1·41–2·54–3·67
Br. melitensis	0·99–1·76–2·53
,,	0·51–1·54–2·57

It will be observed that in twelve of the thirte results quoted, the slope value of 1·9 given by t theoretical curve lies within the 2σ range of t experimental results.

If the hypothesis outlined be true, it follows th the infection or mortality among a batch of anima exposed to a given bacterial cloud depends upon t total number of organisms deposited in the respirato tract of the host, and not upon the time taken deposit them. This, of course, will not be true if t time of exposure is made sufficiently long for i munity processes stimulated by the early depositio of organisms to influence the fate of those deposit later. Thus for a batch of animals exposed to bacterial cloud, it would be expected that a consta mortality or infectivity would be obtained if t aerosol concentration (C) × time of exposure (t) constant.

Results supporting this conclusion have bee quoted by Goldberg and Watkins[3] using *Streptococc zooepidemicus* and *Klebsiella pneumoniae*, while value of $C^{(1\cdot1\pm0\cdot05)}t$ = const. has been obtaine for *B. anthracis* spores and guinea pigs by workers[1] i this department.

Expressed in its logarithmic form, the equatio becomes:

$$\log S = -0\cdot301\,f.$$

It is suggested that bacteriologists, particularly i the field of respiratory infection, might consid whether a simple plot of log survival against do might provide adequate linear representation of the results, as was found to be true for the results t slopes of which are given in Tables 1 and 2.

I am indebted to Dr. D. W. Henderson and M S. Peto for help and advice, and to the Chief Scienti of the Ministry of Supply for permission to publis this communication.

Wave Velocities in the Outer Part of the Earth's Mantle

IITHERTO, wave velocities V in the earth's interior 'e been calculated from the travel times t of earth- ıke waves in shallow shocks computed as a function the epicentral distances Δ. This procedure fails ,t any depth the velocity V decreases with depth ı rate in excess of $dV/dr = V/r$, where r is distance m the centre. In this case a portion of the travel- ıe curve is formed by the arrival of diffracted ves; if these are misinterpreted as direct waves, orrect velocities are found not only for the low- ocity layer, but also (with decreasing errors) for deeper layers. Moreover, discontinuities may be rred when none actually exists.

n 1914, in a different form, the following equation s developed by S. Mohorovičić[1]: $V = V^* r/R$, where s radius of the earth, V is velocity at the depth $h =$ $-r$ of the focus, and V^* is apparent velocity ($d\Delta/dt$) he point of inflexion (distance Δ^*) of the travel-time ve for longitudinal (P) or transverse (S) waves a given shock. Apparently it has not been realized t this equation can be used to calculate the vel- ties of the two waves at a depth corresponding h the focal depth. Neither the time of origin of shock nor the distance Δ^* enters the calculations. e focal depth h of the shock must be known, and a ficient number of reliable time-observations at tance from about 500 km. less to 500 km. greater n Δ^* must be available for finding V^*.

About eighty earthquakes were found listed in the ernational Seismological Summary for which the essary conditions for application of the method fulfilled. Most of them occurred in the Japanese a between 1930 and 1940 at depths from 20 km. 600 km. For years later than 1940 the Summary not yet been issued. Data for a few shocks in eastern and central Mediterranean (depths ween 100 km. and 300 km.), in Roumania (150± ı.) and in the Hindu Kush (250± km.) do not licate any appreciable regional differences in ocity at the depths involved. Average velocities V ngitudinal) and v (transverse) in km./sec., and lues of Poisson's ratio σ at the depths h in km. as follows:

50	100	150	200	250	300	400	500	600
8·0	<7·8	<7·9	8·1	8·3	8·5	9·0	9·6	10·2
4·45	<4·4	<4·35	<4·4	4·45	4·6	4·95	5·3	5·65
0·26	0·27	0·27	0·28	0·29	0·29	0·29	0·29	0·29

These new values agree well with those which had en found by application of the older method to nes of travel of shallow shocks; but they bring t much more prominently the low-velocity layer depths near 100 km. This had been indicated eviously by observations of amplitudes, especially adow zones'[2], at epicentral distances of about 00 km. The new velocity data do not indicate y discontinuity within the range of depth given ove. A sudden increase in velocity at a depth of out 400 km. has been assumed by some to explain e so-called 20°-discontinuity in the travel-time rve. However, this discontinuity is a consequence 'ray optics' produced by the low-velocity layer. e actual velocities in the low-velocity layer may somewhat smaller than those given in the table, ce the resulting decreases in V and v possibly ceed the critical rates of 0·13 and 0·07 km./sec. r 100 km. respectively. Local temperature or other atively small differences at the depths involved may result in a decrease of velocity less than the critical rate in one area and in excess of it in another. Thus P or S or both may show 'shadow zones' of different extent (including zero) depending on the region, and even noticeable differences in time of travel. This could explain the appreciable local differences in the observed amplitudes of P, and S in recorded shocks of a given magnitude at epicentral distances between 500 km. and 2,000 km., even when the velocities at the depths involved are practically the same in all such regions.

Band Spectrum of AsH

IN a letter to *Nature*, Kimball and Bates[1] stated that they have succeeded in obtaining the band spectrum of AsH. The spectrum was excited in a carbon arc run in an atmosphere of hydrogen. The lower electrode formed the cathode of the arc and contained the arsenic. Two bands with origins at 32,380·2 cm.$^{-1}$ and 31,639·9 cm.$^{-1}$ were observed and attributed to AsH. The lines of the band at 32,380·2 cm.$^{-1}$ are represented by the formula

$$\gamma = 32{,}380 \cdot 18 - 11 \cdot 186\, m - 4 \cdot 47\, m^2 + 0 \cdot 0485\, m^3 + 0 \cdot 01027\, m^4.$$

We have tried to photograph the bands mentioned by Kimball and Bates but without success, although a large range of excitation conditions has been used.

It seems probable that Kimball and Bates have been confused by the P and R branches of the $^2\Sigma - {}^2\Pi$ system of CH. Using the frequencies of the lines for the R_1 and R_2 branches of the (0,0) CH band, as listed by Heimer[2], a close fit of the alternate lines is obtained with the lines calculated from the formula given by Kimball and Bates. This is illustrated in the table for a number of lines.

COMPARISON OF THE AsH LINES WITH ALTERNATE CH LINES

R branch of AsH	R_2 branch of CH	P branch of AsH	R_1 branch of CH
32,364·6	32,366·4	32,386·9	32,388·5
340·5	340·6	384·4	384·2
308·5	307·6	373·0	377·1
269·6	268·4	352·9	355·7
224·9	224·6	324·6	325·7
175·8	177·2	289·1	289·1
124·0	126·6	247·3	247·5
071·3	073·7	200·6	201·4
019·9	019·3	150·5	152·1

The other AsH band mentioned by Kimball and Bates was probably confused with the P branches of the 0,0 band of CH and the Q branch of the 1,1 band. The 1,1 band of CH forms a Q head at the approximate frequency of the AsH head mentioned by Kimball and Bates.

Pearse and Gaydon[3] have directed attention to the fact that the band attributed to As_2 by Kimball and Bates is probably identical with the Q branches of the 0,0 CH band.

Relation between Activation Energy and Frequency Factor

It has been frequently observed that in some series of kindred reactions the activation energy of the process appears to be functionally related to the respective frequency factor *A*. For example, when one investigates a reaction taking place in various solvents, one often finds that *E* (the activation energy) and *A* change in the same direction. Such behaviour might indicate that the variation in the nature of the solvent affects the degree of solvation of the transition state, and consequently the activation energy and the entropy of activation (that is, *A*) in the same direction.

It appears that such relations do not hold for series of kindred unimolecular reactions taking place in the gaseous phase. For example, it has been pointed out[1] that the unimolecular dissociation processes of the type:

$$R.CH_3 \rightarrow R.CH_2\cdot + H, \quad RCH_3 = \text{toluene, } m\text{-xylene, } p\text{-xylene and } o\text{-xylene},$$

have a constant frequency factor (apart from the statistical factor of 2 for the xylenes). However, since the activation energies for these processes vary by about 3 kcal./mole only, and the experimental errors involved in their determinations might be as large as ± 2 kcal./mole, this evidence is not very convincing. We have, therefore, been searching for a series of kindred reactions in which activation energies vary over a wide range in order to be able to draw some definite conclusions about the behaviour of the frequency factors.

The series of unimolecular dissociation processes of the type

$$R.Br \rightarrow R\cdot + Br$$

seems to be suitable for such studies. Activation energies were determined for the following decompositions: allyl-bromide, trichlorobromo-methane, benzyl-bromide, benzoyl-bromide, methyl-bromide and phenyl-bromide. All these reactions were studied over a sufficiently wide range of temperatures to yield a reasonably accurate determination of *E*, and the results, computed by the least square method, are summarized in the accompanying table. (The frequency factor for CH_3Br decomposition has been computed by a different method; see, for details, ref. 5.)

R–Br	Ref	E kcal./mole	$A \times 10^{-13}$ sec.$^{-1}$	$t_{[illegible]}$ sec.
$CH_2:CH.CH_2$–Br	4	47·5	0·5	16·0
Cl_3C–Br	5	49	2	80·0
$C_6H_5.CH_2$–Br	4	50·5	1	6·0
$C_6H_5.CO.$–Br	6	57·0	5	0·60
CH_3–Br	5	~67	~2	0·001
C_6H_5–Br	7	70·9	2	0·0001
$\alpha.C_{10}H_7$–Br		70·9	3·5	0·000

Inspection of the table reveals that the frequency factors seem to be approximately constant for a variation in the activation energies of 24 kcal./mole. The approximate constancy of the frequency factors should be contrasted with variations in the rate constants, computed for one temperature, which vary by more than 10^5. This evidence supports strongly the claim that for a series of kindred unimolecular dissociation processes, in which one bond only is ruptured and the molecule is split into a radical anc
free atom, the frequency factor is a constant, c
pending on the nature of the ruptured bond a
independent of the structure of the molecule. Tl
conclusion has been drawn previously[2], but the expe
mental evidence was less satisfactory[3].

The Born Approximation in Electron Diffraction

The Born approximation for the electron wa
scattered by an atom has been universally employe
for the interpretation of electron diffraction expe
ments directed toward the determination of molecul
or crystal structure. There is some justification f
this. Quantitative measurements of diffraction i
tensities performed to test the applicability of tl
approximation for electrons of the energies usual
used in structure work have, on the whole, bee
regarded as satisfactory verifications. In structu
work itself—in the work on gas molecules, f
example—the considerable success resulting from i
use has led to the feeling that even in the presen
of heavy atoms there might not be serious errc
There has perhaps been the implicit faith that wha
ever theoretical refinements were lacking would
least not alter substantially the structures to
derived. We have found, however, that there is
phase shift on scattering, not given by the first Bo
approximation (this is the familiar Born approxim
tion, the first term of a power-series expansion
the parameter $\alpha = -Ze^2/\hbar v$), which is appro
imately proportional to atomic number, depends
angle of scattering, and may become large ar
important. The suggestion of the existence of th
phase shift arose from the cases of uranium hex
fluoride (UF_6) and some other gas molecules.

Interpretations of electron diffraction data fro
uranium fluoride have uniformly led[1] to the conclusi
that the U—F bond-lengths are not all equal; but oth
physical data (spectra, entropy, dipole moment) ha
all been interpreted[2] as demanding the regular octah
dral structure. Altogether, although various argumen
have been made to support the possibility of unequ
bond-lengths, it would seem that the greater weig
of the evidence is against it. The electron diffracti
conclusions for a number of other molecules *M*
are strikingly similar, and show no obvious relati
to known structural chemistry. On the contrar
they all split the bonds into essentially two equ

oups differing in bond-length by amounts approx- ately proportional to the differences of atomic mbers. (The pattern observed for the heavy mole- le I_2 is normal.) This simple behaviour suggests inadequacy of the scattering theory rather than e existence of real structural asymmetries. The ost likely sources of difficulty are the neglect of ultiple scattering (by different atoms) and the in- curacies of the Born approximation for atomic attering. Multiple scattering clearly cannot pro- ice an effect depending strongly on difference of omic numbers, but interference between corrections the atomic scattering can.

We therefore neglect all such effects as double attering and valence distortion, and assume that e scattering by a molecule in practice still may be presented by a superposition of waves $f_j(\vartheta)e^{ikr}/r$ attered by the separate atoms. It is important that e amplitudes $f_j(\vartheta)$ may be complex, although the st Born approximation alleges them to be real. ith $f_j(\vartheta)$ written then as $|f_j(\vartheta)|\exp(i\eta_j(\vartheta))$, the attered intensity is proportional to

$$\sum_{i,j} |f_i(\vartheta)||f_j(\vartheta)|\cos\{\eta_i(\vartheta)-\eta_j(\vartheta)\}\frac{\sin sr_{ij}}{sr_{ij}},$$

here s is the magnitude $|\mathbf{k}-\mathbf{k}'|$ of the difference initial and final propagation vectors and r_{ij} is the paration of the atoms i and j. If the amplitudes e real, the terms of this expression contributed by split pair of distances $r_{ij} = r_e - \delta$ and $r_{ij'} = r_e + \delta$, ith like atoms j and j', become

$$2|f_i(\vartheta)|\;|f_j(\vartheta)|\cos s\delta\,\frac{\sin sr_e}{sr_e}.$$

ince this is just the result for complex amplitudes d $r_{ij} = r_{ij'} = r_e$, if $|\eta_i(\vartheta)-\eta_j(\vartheta)|$ is propor- onal to s, the features of diffraction patterns which ith the Born approximation lead to such splits may ill be interpreted in terms of symmetrical structures. he intensity is evidently highly sensitive to the hase difference only where the phase difference is ose to an odd multiple of $\pi/2$, and in the absence accurate intensity measurements it is only the rresponding behaviour that can be regarded as ell determined. Any moderately smooth and not o great deviations of $|\eta_i(\vartheta)-\eta_j(\vartheta)|$ from propor- onality to s, at other angles, and of the $|f_i(\vartheta)|$ om the Born approximation values, at any angle, uld well remain unnoticed in gas diffraction work.)

Preliminary estimates of the phase shifts $\eta(\vartheta)$ have een made by evaluating the second Born approxima- on, a procedure which may be justified by noting at for screening distances large compared with the ave-length the third Born approximation makes a ther small contribution to the phase. The absolute alue $|f(\vartheta)|$ of the scattered amplitude cannot be ery seriously in error since in the limit (pure coulomb attering) its value is exactly correct. The asymptotic hase shift is essentially divergent, however, and ows how screening, as one might expect, has a most nportant role. In particular, for exponential screen- g ($V(r) = -(Ze^2/r)\exp(-r/a)$), the phase shift for rward scattering has the value $\eta(0) = -\alpha/2$; for rge angles it increases as $-2\alpha\log(sa)$, where a is e screening distance.

The accompanying table illustrates the resulting greement. The 'observed' distance splits are the alues obtained from the observed diffraction pat- rns with the assumption of no phase shift; the lculated values are approximately the ones which ould follow from this interpretation even in the absence of actual distance splits if the phase shift were that given by the second Born approximation for exponential screening. The agreement is remark- able, especially because neither the conventional values $a_0/Z^{1/3}$ used for the screening distances (a_0 is the Bohr radius for hydrogen) nor the approximation of exponential screening itself could be expected to be quantitatively satisfactory. We may add that, to the best of our knowledge, there are no adequately reported gas studies which disagree with the phase shift; those involving heavy atoms and apparently providing support for the Born approximation, for example, are all based on data at s values less than would give the critical relative phase shift $\pi/2$. For crystal diffraction, on the other hand, the phase shift is presumably often important even when not large. We have examined only the intensity anomalies of fluorite[3], cuprous chloride[2] and zinc oxide[4]. Fluorite and cuprous chloride appear to be well explained by the phase shifts; zinc oxide is not.

Molecule	Distance	Apparent split (A.) Observed	Calculated (a)
UF_6	U—F	0 30(b)	0·28
OsO_4	Os—O	0 23(c)	0·24
$W(CO)_6$	W—O	0 24(c)	0·24
	W···O	0·23	0 23

(b) UF_6: Bauer, S. H., and Bastiansen, O., ref. 1. WF_6 and MoF_6: Bastiansen, O., unpublished work in these laboratories.

(c) Sheehan, jun., W. F., thesis, California Institute of Technology (1952).

(d) Mo—C and Mo···O splits assumed equal.

(e) From re-examination of the photographs described by Spurr, R. A., thesis, California Institute of Technology (1942).

(f) Results of Rogers, M. T., thesis, California Institute of Technology (1941), adjusted to a symmetrical (2– /2 2–'/2) split. Spectroscopic evidence (Lord, R. C., Lynch, jun., M. A., Schumb, W. C., and Slowinski, jun., E. J., *J. Amer. Chem. Soc.*, 72, 522 (1950)) indicates C_{4v} symmetry, and the actual I—F lengths may well not all be equal

Details of these matters are being studied and will be reported later. We are also trying to obtain direct experimental verification of failure of the Born approximation by studying the diffraction patterns of suitable molecules over a wide range of electron wave-lengths and by obtaining patterns at sufficiently great s values from molecules of undoubted symmetry.

Note added July 17. The difference in intensity of (331) and ($33\bar{1}$) reflexions from zincblende as reported by Miyake and Uyeda[5] corresponds in sign and possibly in magnitude to the present phase shifts, but the relative importance of these phase shifts and of the dynamic effect discussed by Kohra, Uyeda and Miyake[6] is not clear.

FORTHCOMING EVENT

Friday, August 22

Royal Anthropological Institute (at the University Arts School, Bene't Street, Cambridge), at 5 p.m.—Prof. Kaj Birket-Smith "The History of Ethnology in Denmark" (Huxley Memorial Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chemist (Senior Scientific Assistant grade) in the Central Laboratory Service, Chiswick, with responsibility for section dealing with paints and surface protection—The Staff Officer (F/EV.211), London Transport, 55 Broadway, London, S.W.1 (August 23).

Chief Officer (with executive ability and appropriate qualifications in chemistry) for River Pollution—The Clerk to the Great Ouse River Board, Elmhurst, Brooklands Avenue, Cambridge (August 23).

Lecturer in the Department of Civil and Municipal Engineering—The Secretary, University College, Gower Street, London, W.C.1 (August 23).

Posts in connexion with the construction and development of a linear accelerator in Cambridge—The Secretary, Department of Physics, Cavendish Laboratory, Free School Lane, Cambridge (August 23).

Senior Assistant (Scientific) (temporary, with experience in histology, surgical technique and handling of farm animals) for experimental work—Dr. J. S. Perry, c/o Agricultural Research Council Field Station, Compton, Newbury, Berks (August 23).

Instrument Engineer (with a University degree, H.N. certificate in electrical engineering, or equivalent qualification) in the Research Laboratories at Leatherhead—The Director of Establishments, British Electricity Authority, British Electricity House, Great Portland Street, London, W.1, quoting Ref. AE/269 (August 25).

Senior Lecturers and Lecturers in Home Science (food and experimental cookery, foods and nutrition, and home management), New South Wales Department of Technical Education—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (August 25).

Leaders of Research Sections at the Central Research Establishment No. 2, at Isleworth, Middx.: General Metallurgist with sound practical experience and theoretical background (Ref. TT/513), and a Qualified Engineer with research experience to lead section engaged in work on mechanical engineering problems of the industry (Ref. TT/514)—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting the appropriate Ref. No. (August 30).

Lecturer, and an Assistant, in Botany—The Assistant Secretary of University Court, The University, Glasgow (August 30).

Assistant Biochemist (with a University degree, or equivalent; a knowledge of physiology would be an advantage)—The Pathologist, Group Pathological Laboratory, Lakin Road, Warwick (August 31).

Veterinary Surgeons (preferably with the dual qualification of M.R.C.V.S. and B.Sc. (Vet.Sc.)) in the Field and Research branches of the Department of Veterinary Services—The Secretary, Southern Rhodesia Government, 429 Strand, London, W.C.2 (August 31).

Assistant Lecturer in the Department of Mathematics (preferably with interest in applied mathematics)—The Secretary, University College, Gower Street, London, W.C.1 (September 1).

Junior Lecturer or Lecturer (with an honours degree in botany, zoology or biology) in the Department of Biology—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (September 1).

Research Post in the Department of Metallurgy (applicant must possess an honours degree in metallurgy, preferably with at least one year's research experience, and will be expected to undertake work on age-hardening phenomena, and possibly later, to lead a team of workers)—The Registrar, The University, Liverpool (September 6).

Senior Research Officer for investigations into plant nutrition and biological problems, with particular reference to the cultivation of fruit trees, including citrus, in the Murrumbidgee Irrigation Area (Ref. No. 3940), and a Senior Research Officer (Chemist) to conduct research into various chemical aspects of plant growth and soil problems on the Murrumbidgee Irrigation Area (Ref. No. 3941)—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 6).

Lecturer in Dairying (graduate, preferably with experience in the dairying industry)—The Registrar, The University, Reading (September 13).

Lecturer (with special interests in some branch of electrochemistry) in Chemistry—The Assistant Secretary of University Court, The University, Glasgow (September 15).

Lecturer in Forestry (with a University degree, preferably in forestry, and practical experience of British forestry)—The Secretary, The University, Edinburgh (September 15).

Lecturer (honours graduate with appropriate qualifications and experience) in Sociology at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 15).

Senior Lecturer in Chemical Engineering—The Registrar, King's College, Newcastle-upon-Tyne (September 15).

Assistant Lecturer (graduate in chemical engineering, physics or mathematics) in Chemical Engineering, to undertake work in hydrodynamic problems of chemical engineering—The Registrar, College of Technology, Manchester 1 (September 17).

Senior Lecturer in Medical Bacteriology at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 20).

Veterinary Physiologist at Makerere College (University Colle of East Africa)—The Secretary, Inter-University Council for High Education in the Colonies, 1 Gordon Square, London, W.C.1 (Septe ber 20).

Assistant Lecturer in Botany at Makerere College (Univers College of East Africa)—The Secretary, Inter-University Council f Higher Education in the Colonies, 1 Gordon Square, London, W.C (September 30).

Mackinnon Research Studentship for research in the physic sciences, including chemistry, geophysics, astronomy and engineeri sciences—The Assistant Secretary, Royal Society, Burlington Hou Piccadilly, London, W.1 (October 10).

Director (graduate of a British university and Fellow of t Museums' Association, or equivalent qualifications)—The Directo City Art Gallery, Bristol 8 (October 22).

Assistant (Grade A) in Physics—The Principal, Technical Co lege, Queen Street South, Huddersfield

Assistant Psychologist in the Hospital and associated psychiatr clinics for adults and children—The Medical Superintendent, Sou Warwickshire Hospital Group, Central Hospital, Warwick.

Assistant Research Chemist (organic) in the Hop Researc Department—The Registrar, Wye College, Wye, Ashford, Kent.

Chemist to assist in laboratory dealing with members' day-t day production problems—The Printing, Packaging and Allied Trad Research Association, Randalls Road, Leatherhead, Surrey.

Chemist for research on nutritional aspects of trace elements, particular iodine—The Director, Laboratory of Human Nutritio Churchill Hospital, Oxford.

Electrical Engineer (Senior Experimental Officer grade) to wo in a team engaged on the development of servo-components (Re D.310/52A), and an Electrical or Mechanical Engineer Physicist (Experimental Officer grade) for work on problems co nected with either the generation and distribution of electrical pow in aircraft or electro-technology research in the design and develo ment of aeronautical equipment (Ref. D.311/52A); at the Roy Aircraft Establishment, Farnborough—The Ministry of Labour an National Service, Technical and Scientific Register (K), Almac House, 26 King Street, London, S.W.1, quoting the appropriate Re No.

Engineer at a Ministry of Supply establishment in Hampshir to design and test military engineering equipment, including bridg and other structures, motor-boats and mechanical devices—Th Ministry of Labour and National Service, Technical and Scientif Register (K), Almack House, 26 King Street, London, S.W.1, quotin E.331/51A.

Graduate (male) in Chemistry, Physics or Engineering, wit industrial experience, for the speedy assessment and solution c current problems in industrial packaging (ability to write reports fo the layman is essential)—The Printing, Packaging and Allied Trade Research Association, Randalls Road, Leatherhead, Surrey, quotin Ref. DPTO.

Intelligence Assistant (science graduate), competent in abstract ing, indexing and technical translation work (German and, if possibl Russian or Dutch) (Ref. A.20); and an Editorial Assistant (woma graduate, preferably in science) for preparing publications (Ref. A.21 —The Assistant Secretary, British Coal Utilization Research Associa tion, Randalls Road, Leatherhead, Surrey, quoting the appropriat Ref. No.

Lecturer (with a University degree in physics) in the Department of Applied Physics—The Secretary, Northampton Polytechni St. John Street, London, E.C.1.

Mining Geologist (with B.Sc. degree with honours in minin geology) in Sierra Leone—The Director of Recruitment (Coloni Service), Colonial Office, Sanctuary Buildings, Great Smith Stree London, S.W.1, quoting Ref. 27079/40.

Petroleum Chemists (with a degree in chemistry, chemic engineering or metallurgy) for short Service commissions in the Roy Army Service Corps—The War Office (AG8/CHI), Stanmore, Midd

Senior Lecturer in Biology in the Department of Applie Science, Wolverhampton and Staffordshire Technical College—Th Clerk to the Joint Education Committee, Education Offices, Nort Street, Wolverhampton.

Staff Tutor in Philosophy—The Director of Extra-Mural Studies The University, Edmund Street, Birmingham 3.

Statistician (Scientific Officer or Senior Scientific Officer grad to work on problems and methods in genetics and biological exper mentation—The Secretary, John Innes Horticultural Institutio Bayfordbury, Hertford.

THE PRICE OF COLONIAL DEVELOPMENT

THE recently issued annual report and statement of accounts of the Colonial Development Corporation for the year ended December 31, 1951*, raises even more forcefully than last year's report the question of the future of the Corporation and its place in Colonial development. That place was taken for granted in a debate on aid for under-developed areas in the House of Lords on May 21, when the emphasis, particularly in speeches by Lord Henderson, Lord Milverton, Lord Rennell and others, was laid on the importance of scientific and technical assistance in the development of such areas and on the demands which such development made on scientific and technical man-power. Lord Milverton quoted an estimate that about 150,000 trained men were now being turned out annually from universities, technical training colleges and trade schools in the Commonwealth countries of South and South-East Asia, and Lord Reading, replying on the debate for the Government, dealt with this aspect of technical assistance at some length, asserting that technical assistance meant increasing the degree of knowledge right down the scale to the actual foreman working on the job, and that we in Great Britain ought to be the main source of the experts required.

This need, Lord Reading continued, came at a time when our man-power was stretched almost to its limit; but there was special machinery in the Ministry of Labour for finding such experts as are required. A sub-committee of Lord Hankey's Technical Personnel Committee also was concentrating its attention on overseas requirements. Lord Reading remarked that a chief difficulty was to assure such specialists about their future on their return from posts abroad. The Government had agreed to release Civil servants, if necessary, on secondment, and industry and the academic world could also help by agreeing to the release of certain members of their staffs on generous terms. Men were required of a wide range of skills, and, most particularly, men of eminence and high calibre with a sense of vocation.

Lord Reading thought that Britain would be failing in its duty and at the same time losing something of its status in the world if such men could not be found; and, while the report on the Colonial Territories for 1951–52, issued afterwards, testifies to technical assistance which has been forthcoming for those areas from American experts, a welcome feature of that survey is the extent to which it indicates the man-power situation in the Colonial territories has been improved from British sources. The Colonial Development Corporation's report notes that specialists of various kinds, particularly in accountancy and tropical agriculture, are still hard to find for overseas work, but otherwise has little to say about the trained man-power situation, beyond emphasizing that the Corporation's policy is to employ local men and women where they are available. The high turnover of staff appears to be connected rather with the reorganization and reorientation still proceeding in the second year of Lord Reith's chairmanship.

---

* Colonial Development Corporation. Annual Report and Statement of Accounts for the Year ended 31st December 1951. (Cmd. 167.) Pp. viii+74. (London: H.M. Stationery Office, 1952.) 3s. net.

For the rest, the House of Lords debate followed the lines of discussion on the strategy of world development given in a P E P broadsheet last year. Lord Reading emphasized the success of the Karachi Conference in convincing the countries of the region that greater emphasis should be placed upon agricultural production as distinct from industrial output, and referred to some of the large-scale irrigation schemes such as the Gal Oya project in Ceylon, for 130,000 acres with a hydro-electric scheme providing 75,000 kilowatts, the Bakhra–Nangal scheme in India, with one dam across the Sutlej River little smaller than the Boulder Dam in the United States, the £37 millions project in the Damadar valley, the Lower Sind Barrage scheme of Pakistan to give a further 1 5 million cultivable acres, and the Thal scheme in the Punjab affecting 2 million acres and including irrigation, land colonization and road development. While the debate emphasized the demands which Colonial development must make on the capital, as well as the man-power, resources of Britain, it scarcely emphasized as incisively as a recent series of articles in *The Economist* the price that has to be paid. Important as are certain technical difficulties in Colonial development, such as the improvement of transport facilities, the problem of land tenure and the supply of trained man-power, the crucial issue is that of finance. Where the Colonial territories are concerned, this must, in the main, come from Britain, and the restoration of the United Kingdom to economic health is a prerequisite to Colonial or to Commonwealth development, even side by side with aid from the United States.

In these articles *The Economist* insists that the first step for Colonial development is to create a larger margin of savings at home and a credit surplus on the balance of payments, and that this means reducing our level of consumption relatively to our output. This is the prerequisite to Commonwealth development, and the only alternative to such development is starvation and unemployment. Besides this realistic and harsh gloss on Colonial development, in the light of which the Colonial Development Corporation's report should be considered, there are now available the annual report on Colonial Affairs, 1951–52, already noted, and the Return of Schemes made under the Colonial Development and Welfare Acts in the same period. The report itself was fully debated in the House of Lords on May 28, and the future of the Corporation was a main subject of the debate in the House of Commons on July 17, while a Broadsheet (No. 343) on Colonial Development issued by Political and Economic Planning on July 7 discussed the future of the Corporation in the light of its annual report and the statement made by the Earl of Munster in the Lords debate on May 28.

Looking first at the report itself, the Corporation's operating loss for the year was £1,070,043, as compared with £524,917 in 1950, bringing the accumulated loss sustained by the Corporation in four years to £4,594,599, although for the first seven years the Corporation was relieved from paying interest on t money advanced by the Government. The los were due, however, to the earlier more optimistic a grandiose activities of the Corporation before L Reith became chairman in November 1950. It now claimed that the lessons have been learnt a that any suggestions for immediate large-sc development, such as the Gambia Poultry Far must be treated with particular caution. Stress laid, too, on the way in which estimates have be overtaken in the past by rising costs, particularly marginal schemes, and, other things being equal, t declared policy in future will be to look for expe enced private enterprise partners to share in inve ment and in management. Schemes suggested governments who meet the essential but financial unremunerative elements with their own or wi Colonial Development and Welfare Funds, leavi the Corporation and its partners to take care of t rest, are to be consistently sought in future as o of the soundest lines of development.

On December 31, 1951, there were fifty-thr undertakings in operation, with a sanctioned capit of £35,729,294. Besides the Gambia Poultry Far four undertakings were liquidated during the ye and the report expresses confidence that the end a stage has been reached. Provided the Governme brings its financial requirements into line with i basic intention, confidence can be felt in the C poration, its purpose and its work.

For the second year in succession the anomalo position of the Corporation is emphasized, and t most significant section of the report is that whi discusses the financial background to the Corpor tion's operations.

The Corporation is constituted to operate co mercially; but its financial circumstances and co ditions are at variance with commercial practice a purpose. The Corporation has no funds of its ow the Government providing capital for approv schemes in the form of long-term redeemable loans rates of interest fixed by the Government. The advances have to be repaid, and the rate of intere has this year been raised again to 4¼ per cent, place of the original 3 per cent. The report prote both against the raising of the rate, with the co sequent difficulties in raising other loans or devisi workable schemes, and against the impossibility writing off losses. The result, it is suggested, mu be to deflect the Corporation from its primary purpo of opening up new fields of development unless t Government affords some measure of relief.

The Corporation was not set up to compete wi private capital but to supplement it, because th was obviously not enough private capital for t Colonial developments urgently required. Su development, however, implies adventure and ri at least a long wait and a problematic return, a the report puts the issue bluntly when it says th the motive which established the Corporation was do economic good but to do it without losing mone That motive, it is urged, is being frustrated administrative action through the application standard terms for long-term loans, because t orporation has neither the buffer of ordinary capital bear the risks nor the ability to pass on its costs the consumer, as does a public utility.

Lord Reith's plea was firmly rejected by the overnment in the House of Lords debate on May 28, hough the difference between the Government and pposition in this matter appears essentially to be ne of emphasis, rather than anything more fundaental, as Lord Ogmore suggested. Lord Ogmore laces the emphasis on the Corporation's responsiility to do economic good and appears to think that e Government should be concerned chiefly to see at the Corporation does not force on the Colonial eoples schemes of development which they do not esire. On the Conservative side the emphasis is laced rather on the protection of the taxpayer's oney. Both parties in principle agree to the existnce of the Colonial Development Corporation. erther seems disposed to face the fundamental issue nd to ask those further questions about the purpose nd methods of British Colonial development policy hich, as P E P points out, quite rightly, are escapable once we question the usefulness of the olonial Development Corporation in its present form.

Lord Ogmore in the House of Lords debate advoated first a new financial policy in which the orporation would be allowed to wipe out the cumulated losses and make a fresh start, and cond, that the Colonial Office, Colonial Governents and authorities under the American Point Four rogramme should use the Colonial Development orporation as the agent for their pilot schemes. ther speakers in the debate, like Lord Rennell, ord Balfour or Lord Perth, while agreeing as to the esirability of giving the Corporation a freer hand nancially, welcomed the association of the Corration with private enterprise, and Lord Rennell, particular, urged the need for decentralization. he report itself declares the Corporation's intention transferring in time full managerial, technical d financial responsibility for some undertakings to cal people, and a possible solution to the problem organization would be, as P E P suggests, to volve responsibility on a number of regional rporations, each of which would be expected to eak even after payment of interest, or to make no ore than a specified loss if the financial regulations ere thus relaxed.

There are plainly limits to the extent of such centralization if a central corporation is to remain swerable for the regional corporations, nor can the ssibility of functional devolution be dismissed ithout consideration. That method, which was scussed more particularly by Mr. R. Robinson in e House of Commons debate, might assist coeration with other agencies concerned in the velopment of the backward areas but has its own fficulties, even if it should offer greater economy in e use of the available technical and scientific perts while the present shortage continues. Apart om Viscount Hudson, however, speakers in the ouse of Lords did not concern themselves with this estion of functionalism and the most effective use the scientific expert; but there was some fairly general concern expressed that under the present financial regulations the Corporation may be diverted from its original purpose of filling the gap between what private enterprise is doing in the Colonies and what is being done by the local resources of the Colonial governments and become little more than an investment trust to help private enterprise.

With the drop of nearly 20 per cent in the estimates for 1952–53 for Colonial development and welfare schemes to a total of £13 millions, compared with the original annual ceiling of £17·5 millions and the revised ceiling of £20 millions of the 1940 Act, the gap is likely to be the wider and the consequences of any diversion of the Corporation from its original purpose the more serious. The Earl of Munster's reply on May 28 summarized the Government's policy to the Corporation under five headings. First, the Corporation must be given more time to prove itself. Secondly, in present circumstances, and in the interests both of the Colonies and of the Corporation, speculative projects should be kept to a minimum. Thirdly, the Corporation should continue its efforts to put its own house in order. Fourthly, the Corporation is only one of the agents of Colonial development: it was set up to deal with commercial projects; other projects were the function of Government, through Colonial Development and Welfare and through local public funds. Fifthly, making capital available to the Corporation on artificially favourable terms could not be justified in present conditions.

On the policy of reorganization and caution, the Earl of Munster said further that, before large sums of money were advanced, the Government should attempt to satisfy itself that the Corporation had thoroughly examined all the pros and cons of any scheme, that it had made due allowance for any risks or contingencies, and that it was capable of implementing what it set out to do. Before any new scheme was sanctioned the Secretary of State would require sufficient information to enable him to judge whether a *prima facie* case had been made out. Further, except in special circumstances, someone else besides the Corporation should share in the risk, whether private enterprise or a local government.

The Government's intention to supervise the Corporation more closely, in spite of the Earl of Munster's reminder that the Overseas Resources Development Act laid firmly on the Corporation the sole duty of investigating, formulating and carrying out any projects, is confirmed by what the Colonial Secretary, Mr. Oliver Lyttelton, said in the House of Commons on July 17. Of Colonial development in general, Mr. Lyttelton admitted that over the next decade we would not have collected sufficient capital, although over the next three years this would not be the dominant factor: shortages of steel and of skilled labour, delays in importing machinery and the indifferent organization of local resources were likely to be the limiting factors.

Turning to the Colonial Development Corporation he reiterated the view that the Corporation was intended to act as a commercial concern and to pay its way, taking one year with another. Entirely uncommercial projects, such as much research and experimental work, were outside the ambit of the Corporation, and the Corporation should not undertake projects which were unlikely to yield a gilt-edged rate. The Colonial Secretary then delineated more precisely the four criteria which would determine his approval of capital grants for the Corporation, at least one of which must be satisfied. He would inquire, first, whether the Colonial Government in the territory concerned was willing to participate if it had the money to do so; second, whether any local knowledge and experts had been mobilized, for example, on the board of the operating company in that territory; whether any local capital had been offered and accepted participation; and whether the Corporation had tried to associate itself with any company in the United Kingdom or elsewhere carrying on the same kind of business.

Exception can scarcely be taken to these criteria by those who have the interests of the Corporation and of the Colonial territories at heart; but it remains to be seen whether in practice they may not amount virtually to abolishing the Corporation. They do not dispose of the basic argument in the Corporation's report that its activities are already too severely confined by the financial rules which govern its operations, and the merits of a more vigorous policy and the ways in which such a policy could be pursued deserve closer attention than Government or Opposition spokesmen were disposed to give them in either debate. The P E P broadsheet already mentioned is of particular interest here. Apart from its close analysis of the activities of the Corporation and of the factors which inhibit both private investment in the Colonies and investment by a Government corporation, the broadsheet discusses the possibilities of new policies in this field.

The broadsheet frankly recognizes the difficulties on either side, and its discussion of such matters as the financing of experiments and pilot schemes is realistic. It finds no sound reason for the proposal to form a new organization for research and pilot projects, and while it does not insist as firmly as *The Economist* articles on the price to be paid for Colonial development and welfare, it points out clearly enough that the answer to be given to the financial questions regarding the Corporation's future depend both on the judgment as to how vigorous a policy the Corporation should pursue and the view taken of the broader issues of Colonial development. The right questions are asked, and the broadsheet is a contribution to the clearer understanding of the aims and methods of development without which no satisfactory policy can be framed. As the broadsheet comments, it is not much use to create institutions without any very clear idea of what they are intended to achieve. The dominant impression left by the recent debates is that, while both Government and Opposition wish to continue the Colonial Development Corporation, neither have any very precise ideas as to what it is intended to do, the real basis of selection of projects, of the relation of its activities to Colonial welfare and whether and how there should be closer collaboration with the Colonial Development and Welfare Fund.

FLUORESCENCE OF ORGANIC COMPOUNDS

Fluoreszenz organischer Verbindungen
Von Prof. Theodor Förster. Pp. 312. (Göttingen
Vandenhoeck und Ruprecht, 1951.) 32.50 D. mark

FLUORESCENCE methods of estimation exten
to much lower ranges of concentration than thos
based on light absorption, since the latter work b
differences or ratios between light beams with an
without absorption, whereas fluorescence, beside
being very specific, is measured from a zero whic
can be made very low by paying sufficient attentio
to apparatus design. Within recent years the need
which have arisen in various fields to estimate ver
small quantities of certain vitamins, uranyl salt
aromatic hydrocarbons, etc., together with develop
ments of photoelectric cells, electron multipliers an
electronic circuits, have caused a number of fluor
meters to be put on the market. The result has bee
a great widening of interest in the subject of fluo
escence, the mysteries of which have until lately bee
the cult of very few. On the basis of the reversib
nature of light absorption, it might be expected the
fluorescence would be a common and relatively simp
phenomenon; it is, however, rare and easily affecte
by disturbing factors which provide many pitfalls fo
the unwary experimenter.

Prof. T. Förster's book is not immediately intende
for the instruction of beginners in the avoidance
errors in measuring fluorescence; although practic
methods are dealt with, commercial fluorimeters a
not described in detail. It is a critical, accurate an
up-to-date academic account for the serious studen
of each of the various aspects which have bee
explored by individual workers, with very complet
references. The chapters include discussions of th
relations of the structure of molecules and their powe
to fluoresce, the theoretical principles of light absor
tion and emission, fluorescence spectra, quantu
yields, measurements of mean life before emissio
polarization phenomena, and 'quenching'. For th
practical worker, 'quenching' is a matter of th
greatest concern; it refers to the reduction in th
fluorescence of a solution due to rise of temperatur
increase of concentration, or the addition of foreig
'quenchers'. Most molecules, which are not fluo
escent, are 'quenched' by 'internal conversion', th
is, the excitation energy is converted into molecul
vibrational energy by a radiationless process formal
explicable as a crossing of potential energy curve
The work of G. N. Lewis and Kasha has shown th
in many cases this involves the intermediate form
tion of 'triplet' excited levels of long life a
potentially important photochemical possibiliti
Collisions with foreign 'quencher' molecules may al
produce triplet levels, or may form radicals t
photochemical reactions of which have been studi
by Weiss and M. G. Evans. The relationship betwe
triplet production and radical formation is a proble
of great present interest. At very low temperatur
and under appropriate conditions, triplet levels gi
a luminescence of their own, with a very long me
life, and affording new means of characterizi
molecules which may never exhibit norm
fluorescence.

Another interesting field in which Prof. Först
has himself made notable advances is that
resonance energy transfer between molecules.
crystals such as anthracene, and in solutions

ighly fluorescent substances, electronic energy may ass from molecule to molecule before radiation of uorescence occurs. The distance over which such ansfers take place may be as large as 50 A. or more, o that the effect may be observed in solutions of oncentration 10^{-4}–10^{-3} *M*. Resonance transfer is of nportance in the study of photosynthesis by chlorohyll in plants and in the use of fluorescent substances s scintillation counters for radioactive rays. After ong hiding its light under a bushel, fluorescence is ow being brought out into the daylight, and rapid dvances in practice and theory may be confidently redicted.

E. J. Bowen

TEXT-BOOKS OF ORGANIC CHEMISTRY

Organic Chemistry

By Louis F. Fieser and Mary Fieser. Second edition. Pp. xv+1125. (Boston, Mass.: D. C. Heath and Co.; London: George G. Harrap and Co., Ltd., 950.) 7.50 dollars; 42*s*.

Organic Chemistry

By Dr. A. F. Holleman. Revised by Prof. J. B. Vibaut. Translated from the sixteenth Dutch dition by Dr. Samuel Coffey. Pp. xiv+660. (New York and Amsterdam: Elsevier Publishing Co., nc.; London: Cleaver Hume Press, Ltd., 1951.) 5*s*.

Organic Chemistry

By Dr. I. L. Finar. Pp. xv+696. (London, New York nd Toronto: Longmans, Green and Co., Ltd., 1951.) 0*s*. net.

MOST organic chemists have their own ideas concerning the perfect text-book for their ubject, and a surprisingly large number possess the nergy to bring their conceptions to fruition. As a esult, students at all levels have a wide choice of uide to explore what Wöhler termed the "monstrous nd boundless thicket" of organic chemistry.

The popularity of the first edition (1944) of the ext-book by Prof. and Mrs. L. F. Fieser was due ot only to its wide scope and up-to-date treatment ut also to the clarity, readability and occasional umour of its exposition. These characteristics are etained in the new edition, which incorporates the ignificant advances of the past six years. Two major missions in the first edition have been remedied with he introduction of chapters on reaction mechanisms a triumph of well-written condensation) and on eterocyclic compounds. Space for these inclusions as been found by substantial pruning of previously ver-written chapters (for example, steroids and uinones) and by adaptations of the format. Only ne misprint could be detected, and the printing and inding are admirable. The pre-eminent usefulness f this book for all classes of student arises as much rom its enthusiasm and feeling for the subject as rom the attributes described above.

Roughly comparable in scope is the text-book of Prof. A. F. Holleman, revised and adapted by Prof. . B. Wibaut; but the treatment tends to be oldashioned and rather disjointed. Discussion of the sual homologous series is carried through with ainstaking thoroughness; the more advanced topics re, however, treated much more cursorily. There are ome startling omissions. The enormous advances in the separation of the constituents of protein hydrolysates are dismissed in four lines with no reference to paper chromatography. Again, in the section dealing with benzenoid substitution the concepts of inductive effect, mesomeric effect and hyperconjugation are not even mentioned; there is a similar lack of reference throughout to modern ideas concerning reaction mechanisms. It would not be inaccurate to classify the work as a present-day representative of an older type of text-book. The translation on the whole reads smoothly, although it is hoped that, in any future edition, the monstrosity "higherhydric" will be eliminated. The printing and binding are good.

The content of Dr. I. L. Finar's book is deliberately restricted to the basic groundwork of the subject and does not deal with topics such as the more complex natural products. Although thus limited in scope, the treatment is both complete and modern with full mention of the unifying physico-organic concepts. In particular, this seems to be the first organic chemistry text-book to include an elementary exposition on molecular orbitals, and recently introduced reagents and techniques (for example, lithium aluminium hydride) are discussed. The style is clear and readable, and the book can be recommended as providing a sound foundation for more advanced study.

R. A. Raphael

TEMPORAL INTEGRATION AS A CLUE TO MIND

The Organization of Behavior

A Neuropsychological Theory. By D. O. Hebb. (Wiley Books in Clinical Psychology.) Pp. xix+335. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1949.) 32*s*. net.

SINCE its publication, Prof. D. O. Hebb's book has been widely and sympathetically discussed, and has won a place among the more notable contributions to current theory in physiological psychology. Its author was unusually well equipped for the ambitious task he undertook, namely, to formulate a theory of behaviour embodying recent developments in the neurophysiology of the brain as well as in experimental psychology itself.

Dr. Hebb allies himself at the outset with those theorists in psychology, sometimes called 'reductionists', who have no hesitation in introducing neurophysiological concepts to explain human behaviour. The 'non-reductionists' take the view that this cannot be done without injury to the psychological facts. Dr. Hebb attempts to safeguard himself against criticism from this direction by not denying or ignoring the complex facts of behaviour. He does not deal with mind by reducing it to the level of what is now known about the body; he rather suggests highly complicated forms of neural interaction which may help to explain what is now known about mind. Here his main contribution lies in his conception of *temporal* integration in cerebral activity. This conception has received strong support from the independent work of H. F. Harlow on 'learning sets' and of H. O. Mowrer on the persistence of self-defeating behaviour.

The theoretical gap which Dr. Hebb proposes to fill he attributes to the failure of neurophysiology to explain the events that occur in cortical transmission, that is, during the interval between the arrival of an excitation at a sensory area and its departure from the motor area of the cortex. It is this failure which, in his view, has made it impossible for psychology to develop an adequate treatment of thought. He begins by directing attention to the apparent incompatibility between perceptual generalization, on one hand, and the stability of memory, on the other, and suggests a way out of this dilemma by effecting a compromise between configurationism and learning theory. At this point he brings in his distinction between perceptual unity and perceptual identity. The former—that is, the figure-ground relationship—he concedes to the configurationists, is sensorily determined and, so to speak, is 'given' in experience. The latter, he insists, is the result of learning. He is consistent in supposing that the mnemonic trace involves structural change and that perception depends, not on a pattern of excitation, but on the excitation of specific cells.

The theory of the book briefly amounts to the following. The more constant the stimulation from an object, the more readily it will be identified and so evoke a response. Repeated stimulation results in the formation of 'assemblies' of association-area cells, which facilitate other such assemblies. After stimulation has ceased, a cell assembly can act for a short time as a closed system and so prolong the interval during which structural change can occur. A series of cell assemblies produces a 'phase sequence', of which human thought is the most extended example. A phase sequence is a process that co-operates fully with external stimulation without being fully controlled by it, thus allowing for 'autonomous cortical processes' and for the psychological phenomena of expectancy and set.

The theory is developed in considerable detail, and, though it is speculative, the speculation is specific and thus renders it subject to the tests of observation and experiment as further evidence becomes available. Its usefulness in clarifying problems of perception, learning, motivation, and intellectual deterioration is a first step towards its verification. John Cohen

A REVIEW OF SCIENTIFIC INSTRUMENTS

Journal of Scientific Instruments

Editor: Dr. H. R. Lang. Vol. 28 and Supplement No. 1, 1951. Pp. xvi+388+iii+80. (London: Institute of Physics, 1951.) Bound, £3 12*s*.; unbound, £3.

The *Journal of Scientific Instruments*, the monthly publication of the Institute of Physics, deals with the principles, construction and use of scientific instruments and is produced by the Institute with the co-operation of the National Physical Laboratory. When the *Journal* was started in 1923 it was the only periodical devoted to the subject of scientific instruments, and it soon obtained a high reputation among physicists and manufacturers of scientific instruments. This high reputation has been maintained through successive editorships. The present editor, Dr. H. R. Lang, the secretary of the Institute, has been responsible for Vols. 9–28, covering the period 1932–51. His task has not been made easier in recent years, first by war-time restrictions, then by post-war difficulties due to increased and continually rising costs of production, and, more recently, by the added responsibility of the publication of a sister monthly, the *British Journal of Applied Physics*. Nevertheless, a comparison of Vol. 28 with previous volumes shows that not only all the regular features and the high standard of the articles and book production have been maintained, but also that, in Vol. 28, the innovation of an attractive and informative supplement of papers on vacuum physics has been introduced. The editor and the advisory committee, under the chairmanship of Dr. R. S. Clay, are thus to be congratulated for their fortitude and their progressive attitude.

Vol. 28 contains four special articles, ninety-six original contributions, laboratory and workshop notes, reviews and notices of new books and descriptions of new instruments, materials and tools, in addition to the previously mentioned supplement. The range of subject covered is wide and most branches of physics are represented. Rarely does an author have more than one contribution; but Dr. Kantorowicz, formerly at the National Institute of Medical Research, London, and now at the Pametrada Research Station, Wallsend-on-Tyne, has no less than five laboratory and workshop notes in the volume. All the contributions are remarkably free from errors and misprints. Since quite a high percentage of the papers show by the dates of receipt that they required modification before final acceptance, it is suspected that the concise and effective form in which they appear is in no small part due to the conscientious and devoted manner in which the referees have carried out their arduous and voluntary task. It is a pleasure to record that the *Journal*, as it richly deserves, continues to prosper and that its circulation, both to members and non-members of the Institute, is on the increase. It is excellent value for the price. S. Weintroub

MAMMALS OF THE OLD WORLD

Checklist of Palæarctic and Indian Mammals, 1758 to 1946

By J. R. Ellerman and T. C. S. Morrison-Scott. Pp. vi+810. (London: British Museum (Natural History), 1951.) 65*s*.

All students of mammals welcome the appearance of this volume and are greatly indebted to the authors for their painstaking labour in providing a much-needed corner-stone in the structure of systematic mammalogy. The list, based on the unrivalled collections of the British Museum (Natural History), is not merely one of the working tools that every systematist must make for his own use but is also a critical revision of the mammals inhabiting an immense area of the earth's surface. It deals with mammals of the palæarctic and Indian regions, thus linking up with the already existing lists of the mammals of the Malayan and Ethiopian regions.

The authors give critical introductory paragraphs for each order and family, and indicate the diagnostic characters of each genus and species by reference to the appropriate works or by specially devised keys. The distribution of each species is approximately shown, though "it should be remembered that the distributions of many mammals are imperfectly known and that the ranges of many of the larger mammals are shrinking every year".

In the time covered by this revision, from the tenth edition of Linnæus to the end of 1946, an immense number of forms has been described. With the accumulation of adequate collections for critical nparison it has become evident that many of the ms were separated and named on insufficient owledge of their variation, and the authors are le to relegate a large number of specific and sub-ecific names to the synonymy. They have, however, ly indulged in 'lumping' to the extent justified by e evidence, and they believe that there is probably uch more to be done ; they have therefore arranged e sub-species in order of priority for the convenience subsequent revisers. Nevertheless, the authors cognize no fewer than 809 species of mammals in e palæarctic and Indian regions as here defined.

Nomenclatorial difficulties are dealt with in a way at will commend itself to all right-thinking zoo-gists ; the authors mention some of the works that ve proved most troublesome, and list a number of mes that they have submitted to the International mmission on Zoological Nomenclature to be placed the "Official List". "There are workers who seem take a delight in bedevilling zoology with esoteric anges of nomenclature. . . . Zoologists who dis-ver a name which would cause confusion or incon-nience, though antedating a later but currently lopted name, should refrain from publishing their nfortunate find, and instead should hurry it off to e Commission for burial in the appropriate 'Index', the same time requesting the Commission to place the appropriate 'List' the later but currently used me. These are the principles which we have deavoured to follow. . . ."

It is fitting that this book is dedicated to the emory of the late James Lawrence Chaworth-usters, who had spent much time on the synonymies the species of palæarctic mammals. The results of s patient and lengthy researches into the type calities and the dates of publication of species scribed in the eighteenth and early nineteenth nturies are incorporated in this volume, especially r the Insectivora, Chiroptera and Rodentia. Had haworth-Musters lived, he would undoubtedly have ken a large part in the work of preparing this list ; s death was a great loss to systematic mammalogy.

The paper, printing and binding of this work leave thing to be desired, and are fully in keeping with e high standard set by the publications of the ritish Museum since the end of the War. This lendid volume brings great credit to all concerned its making.

L. HARRISON MATTHEWS

FLORA OF ARIZONA

rizona Flora

y Thomas H. Kearney, Robert H. Peebles, and llaborators. Pp. viii+1032+32 plates. (Berkeley d Los Angeles: University of California Press; ondon: Cambridge University Press, 1951.) 56s. 6d. et.

ARIZONA, one of the largest of the American States, being almost the size of Italy with early 114,000 square miles, presents a wide range of pography. The land rises from almost sea-level to plateau at an altitude of well over 12,000 ft. and cludes the mile-deep Grand Canyon. The rainfall as a yearly average which varies from as little as ree inches to nearly ten times that amount, while e frost-free period may be as short as three months r extending nearly throughout the year. In accord-nce with these variable conditions, the vegetation, hile in general of a dry type, ranges from desert to evergreen pine forests. The environments provide a remarkable range of ecological conditions and support the flora of some 3,370 species with which this work deals, comparable in extent and diversity to that of the whole of France. Moreover, the flora embraces a considerable proportion of endemics, more than 160 in number. The vegetation is notable for the unusually high representation of three families, in particular the Cactaceæ, seventy-one species, the Euphorbiaceæ, eighty-four species, and the Polygonaceæ, ninety-four species. It is undoubtedly the desert vegetation for which Arizona is most famous, and especially the Cactaceæ, in which the area is so rich, including twelve species that are endemic. Of these cacti, *Carnegiea gigantea*, the State flower of Arizona, is the best known and the largest, attaining a height of fifty feet and possibly living for 150–200 years. Its fruits and seeds furnished food for the native Indians. At the other extreme, in respect to size, is the endemic and very local *Navajoa peeblesiana*, with rounded stems only 3 cm. high bearing spongy spikes. It is the members of the Cactaceæ that are mostly portrayed in the forty-five reproductions from photographs with which this work is illustrated.

The Euphorbiaceæ are represented by no less than forty-seven species of *Euphorbia*, while in the Polygonaceæ the genus *Eriogonum* is particularly rich with fifty-seven species. The largest genus in the flora is *Astragalus*, represented by more than seventy species, of which eight are endemic. Some of these are highly toxic because of their remarkable capacity for accumulating selenium from the soil. Others, too, though reported not to contain selenium, are nevertheless very poisonous and cause the famous loco disease of sheep and cattle.

Another well-represented genus in the Scrophulariaceæ is *Pentstemon*, with fifty-eight species, of which two are endemic. Needless to say, the flora includes a number of very peculiar types, not least curious being the parasite *Ammobroma sonoræ*, of which the only visible portion above the ground is the saucer-shaped receptacle bearing numerous small flowers that open in concentric rings.

The introductory matter of this flora provides a useful summary of the topography and climatic conditions and other aspects of the physiological environment, with a very brief account of the geographical elements that comprise the flora. The great bulk of the text consists of keys to the families, to the genera within each family, and for each genus a key to the species. No full descriptions are provided for the species themselves; but the information in the dicotyledonous key is somewhat fuller than such usually provides. In addition to this, the distribution of each species in Arizona is stated, together with its altitudinal range, the type of habitat, time of flowering, and the general geographical distribution. The proof of the full value of such a work must be its use in the field, and it is for the convenience of this purpose that more extended descriptions have been sacrificed. If one regrets that decision, it is largely because these condensed diagnoses whet the appetite for a full account of this fascinating flora.

The chief criticism that one has to level against this book is that the page headings have been entirely wasted. If, instead of merely "Arizona Flora" or "Flora of Arizona" which appear throughout on alternate pages of the text, the relevant order or genus had been cited, it would have greatly assisted the reader in converting a redundancy to useful information.

E. J. SALISBURY

ARID ZONE RESEARCH

THE Advisory Committee on Arid Zone Research, set up by Unesco, recommended at its first meeting, held in April 1951, that special attention should be given to the collection of information and the discussion of problems concerning arid zone hydrology and particularly water supply. Thus on the Committee's advice, Unesco obtained and is printing a series of reports on hydrology and its problems in the arid areas of the world written by a number of authors, together with climatological maps of such areas.

Unesco in 1952 also organized, jointly with the Government of Turkey, a symposium on "Hydrology of the Arid Zone" which was held in Ankara during April 25–29. This conference was opened by the President of the Turkish Republic. Papers were given by representatives of about a dozen nations and dealt with: (1) the statics and dynamics of underground water; (2) its physical and chemical properties; (3) the hydrological balance and the effects of water utilization; (4) methods of prospecting for water; (5) the relation of hydrology to other sciences. Each of these subjects was introduced by a general review paper, after which papers were given on particular aspects of it. Many of the papers aroused considerable interest and provoked active discussion, and it was generally thought that the conference had proved very useful. Its proceedings will be published. Visitors taking part in the symposium received very kind hospitality from the Turkish authorities during and after the meeting. This included an excursion to part of the arid area of Central Turkey.

The Advisory Committee on Arid Zone Research also held its third meeting in Ankara in April. In its recommendations it followed its policy of giving priority to the collection, dissemination and discussion of information. Thus it recommended the preparation and printing of reviews of research on: (1) arid zone plant ecology; (2) sources of energy available in arid regions. Symposia on these two subjects were proposed for 1953 and 1954 respectively. On the Committee's recommendation, Unesco gave financial help to the Government of Israel in publishing the proceedings of its Symposium on Desert Research that was held in Jerusalem during May 7–14 (see below) and to the Institute of Biology (U.K.) to help towards the travel expenses of participants in its symposium on the "Productivity and Biology of Hot and Cold Deserts" that is to be held on September 25–27 next in London.

Unesco has asked its member States to appoint persons from whom advice may be obtained in a number of fields related to arid zone research. Such panels of experts have now been appointed by fifteen States and have already proved useful. The Committee recommended that this scheme be extended.

It also considered the preparation of a handbook that should give advice on the collection of basic data needed in planning the development of arid areas.

A scheme is now in operation in which certain research institutions, carrying out research in arid areas or concerned with their development, may be designated as suitable for the exchange of personnel and information and for the reception of visiting scientists. After considering their qualifications, the Committee recommended that the following institutions be added to those already designated. Particulars about them can be obtained from Unesc (a) Fen Fakultesi Botanik Enstitusu (Institute Botany, Faculty of Science), University, Ankar Turkey; (b) Department of Botany and its Ge botanical Research Laboratory of the Negev, Hebre University, Jerusalem, Israel; (c) Institut França d'Afrique Noire, Dakar, French West Afric (d) Jaswant College, Jodhpur, India; (e) Tohu Islah ve Deneme Istasyonu (Seed Improveme Station), Eskischir, Turkey.

The Committee considered the question of givi travel grants to men of science desiring to carry o research or make field studies abroad. It reco mended that the Director-General might give suc assistance in a limited number of cases provided "(a) that the proposed research or field study com within the scope of the Arid Zone Programme (b) that the work is of importance to several Unes Member States having arid and semi-arid areas (c) that the results of the work will be freely availab to the public; (d) that the request for transportatio assistance by the individual is supported by th Unesco National Commission in his country; (that the individual has obtained approval for th research or field study from the appropriate authorit at the institution or in the area in which the wor is to be done".

On the research side the Committee recommende a small grant to assist in the study of the vegetatio on certain nitrate- and sulphate-rich soils in Sout Algeria.

H. G. THORNTON

AN international symposium on "Desert Research' organized by the Research Council of Israel in co operation with Unesco, was held in Israel durin May 7–14. The growing interest in research devote to various aspects of arid zones and their reclamatio has been further stimulated by Unesco's activitie especially by the establishment of the Arid Zone Re search Committee, and by the Unesco symposiu on "Hydrology of the Arid Zone" (see above). Th symposium in Israel was the first of its kind to b organized by a member-state of Unesco, and th first the programme of which did not restrict itself t one special subject of arid zone research but include several topics, and gave the opportunity for scientist in those fields of research to get an integrated pictur of various aspects of desert research.

About fifty-five men of science from eightee countries attended the symposium. At the openin ceremony in Jerusalem guests were welcomed b the Prime Minister, Mr. D. Ben-Gurion. Dr. Shen-Y chief of the Bureau of Flood Control of the U.N Economic Commission for Asia and the Far East brought the greetings of the Secretary-General of th United Nations, and Dr. F. J. Malina, of the Natura Science Department of Unesco, spoke on behalf o the Director-General of his organization. A shor outline of the significance of the symposium was give by Dr. W. C. Lowdermilk, F.A.O. Adviser to th Government of Israel, who presided over th symposium.

Three days were devoted to scientific sessions i Jerusalem, the next three days to scientific excursion in the Negev, the Coastal Plain, and Galilee, and final day to further scientific sessions in the Institut of Technology, Haifa.

Among the general papers were those by Leighly nited States) on “Dry Climates : their Nature and stribution” ; Kellogg (United States) on “Poten- lities and Problems of Arid Soils” ; Monod (France) “Biology and Arid Regions” ; and Bagnold (Great itain) on “The Surface Movement of Blown Sand Relation to Meteorology”. According to Prof. B. Leighly, the extent of areas with a deficient ater balance can be correlated with the wave- ttern of the mean isobars at a height of 3 km. ove sea-level. Dr. D. Amiran (Israel) pointed out at the boundaries of semi-arid areas in Israel are ntinually shifting except where they are nearly ed by the topography of the area, as in the Jordan t.

There was complete agreement with Dr. E. C. ellogg in his emphasis on economic and social ctors in the utilization of arid and semi-arid soils, d interest in his view that in this area under- azing as well as over-grazing constituted a danger ith regard to soil erosion.

After a survey of the present position of biological search for arid zones by Prof. Th. Monod, Dr. R. A. gnold spoke on the mechanism of soil and sand ansport by wind and explained his theory on the lation of the formation of sand ridges to the thermal ructure of the atmosphere. Prof. C. W. Thorn- waite (United States) referred to some further data support of Dr. Bagnold’s figures.

Papers on climatology and meteorology in arid and mi-arid regions were read by Prof. P. Meigs (United ates), Prof. C. W. Thornthwaite (United States) d Mr. S. Duvdevani (Israel). Prof. Meigs dealt ith the preparation of homo-climatic maps, and owed in particular a map of Israel and Jordan. e discussed the parameters to be used in the eparation of these maps. Prof. Thornthwaite dealt ith problems of water planning, stressing the portance of assessing potential evapo-transpiration, e amount of which can under certain circumstances found by using phenological indications as curately as by special measurements. The dis- ssion on this paper was concerned with the iformity of the water-storage capacity of soils, apo-transpiration from various growths, and the e of atmospheric measurements to ascertain rigation needs ; for a first planning the nature of e crop is not considered of critical importance in sessing these needs. Mr. Duvdevani had measured e dew deposit on a prepared surface at various ights above the ground. The deposit at stations m. or less above the ground depends on the topo- aphy, the soil and the season, and particularly on e water content of the uppermost layer of the soil ; ove a wet soil the deposit decreases upwards, above dry soil it first increases and then decreases. The ysical meaning of these measurements was raised the discussion without conclusion.

Six papers were read in the Section on Soils. Prof. S. Hills’s (Melbourne) lecture dealt with the lationship of physiography and climate, and with e influence of former physical conditions (as found om ‘fossil’ lateritic soils and sand ridges now earing vegetation) and geomorphic features and atterns of natural drainage. The dramatically dden and devastating effects of locally produced ods in desert areas was the main subject of Dr. . C. Lowdermilk’s lecture. Prof. A. Reifenberg srael), in a historic survey, showed the relationship the encroachment of the desert to stable social nditions of government. Prof. G. Aubert (France) stressed how soils science had applications in the planning of irrigation, and Prof. S. Ravkovitz (Israel) dealt with the wind transport of soil material ; according to him the salts in the loess soils in the Southern Desert of Israel were probably wind-borne from the Dead Sea. Dr. G. Leone’s (Italy) lecture on the stabilization and re-vegetation of coastal dunes of Tripolitania introduced a discussion which stressed a similar state of affairs in this respect in the whole Mediterranean area.

The lectures in the Section on Biology were many-sided, embracing human physiology, general ecology, zoology and phytology, all with emphasis on desert environment. Dr. W. S. Ladell (Nigeria) gave a review on the physiology of life in high ambient temperatures which included the result of his research during the past ten years. He stated that Europeans temporarily resident in a tropical climate learn to tolerate severe heat with less discomfort than the local inhabitants. He refuted the theory that warm climates are detrimental to health and to productive work. He held the view that white settlers in hot regions had succumbed, when they had succumbed, to disease rather than to climatic factors. Ladell also discussed the physiological changes in the course of acclimatization to heat, the role of sweat and chlorine loss and of the central regulation mechanism involved. He stressed the point that in order to become acclimatized one has to expose oneself and not carefully to avoid exposure. Prof. F. S. Bodenheimer (Israel) spoke on the physiology of animals in arid zones with special reference to the frequent occurrence of dark and black colours.

Prof. F. W. Went (United States) spoke about the different germination mechanisms of desert plants which inhibit their germination at the wrong temperatures or after insufficient rains. He stressed the role of water in the germination of desert annuals. When the soil was kept wet all the time no germination occurred for many species. The reason for this lies in the presence of germination inhibitors inside the seeds, which are not leached out by small amounts of precipitations. With too much rain not only the inhibitors but also a growth-promoting substance is leached out. The inhibitors are formed continuously as soon as the seeds are wet. Dr. H. G. Thornton (Great Britain) dealt with his new approach to microbiological research work on desert soils, and Prof. Ch. Killian (France) gave a description of the vegetation of the Chott Hodna (Algiers) and analysed its edaphic conditions. The results are indicator values of the various plant communities, particularly with regard to chemical properties. Dr. B. T. Dickson (Australia) and Dr. P. C. Duisberg (United States) dealt in particular with plants in arid and semi-arid zones, Dickson with the Australian experience of transplanting plants into Australia, and Duisberg with the commercial utilization of desert plants from North America. Afforestation in arid areas was the subject of Sir Harold Glover’s (Great Britain) lecture, which contained advice for planting, seeding and felling in such a way as to minimize the encroachment of the desert. Prof. M. Even-Ari (Israel) gave a short account of the water balance of desert plants, especially their adaptation to the dry season by decreasing their transpiring surface. Dew formation and active condensation of water vapour out of the atmosphere possibly constitute additional water sources for these plants. In the discussion, Prof. Went pointed out that the real suction forces of plants are apparently much stronger than those obtained by cryoscopic measurements of osmotic values.

Prof. A. Bonne (Israel) and Dr. M. Ezekiel (F.A.O.) presented the point of view of the economist and explained the importance both of economic planning and of general economic and statistical surveys of food requirements. Prof. M. R. Huberty (F.A.O.) explained the structure and purpose of the Food and Agriculture Organization with special reference to its activities in the field of ground-water studies.

Introductory to the excursions, Mr. P. L. O. Guy (Israel) gave an account of the remnants of the soil and water conservation service which existed in the Kurnub upper-catchment area during the Byzantine period and suggested that the site should be rebuilt as an experimental reserve; Mr. A. de Leeuw (Israel) outlined the overall irrigation scheme for Israel with special emphasis on the problem of water storage.

In the session held in Haifa, Mr. E. W. Golding (Great Britain) told of recent British experience on the utilization of wind-power for the generation of electricity by windmills of modern type, and gave a general discussion on the economic exploitation of wind energy with particular reference to this region. The remaining papers of the last day dealt with problems of ground water and water in soils. Dr. P. Danel (France) dealt with the physics and the measurements of the flow of ground water and with the application of the methods of measurement which he and his co-workers in Grenoble had developed. Dr. L. A. Richards's (United States) papers also dealt largely with the technique of measurements, in this case with the physical properties of soils, especially as regards their power to retain water. The relevance of such measurements to irrigation methods was discussed, as well as the foundations of the new subject of soil physics. The paper of Dr. A. N. Khosla (India) was read by his colleague, Dr. R. D. Dhir, and dealt with the relation of surface water and ground water in arid zones. He gave a simple formula which he has applied successfully to several catchment areas in India to determine the yearly run-off from catchment areas. The formula is based on monthly average temperatures only. In the discussion it was pointed out that Dr. Khosla's method may be correlated to Thornthwaite's method of evapo-transpiration. Prof. L. Picard (Israel) reviewed the history of ground-water investigations, and Dr. M. G. Drouhin (Algiers) spoke on hydrological studies in desert regions.

In the closing session Sir Ben Lockspeiser (Great Britain) summed up his impressions of the conference, followed by a discussion to which, among others, Kellogg and Monod made valuable contributions. It appears that the main lessons to be learned from this symposium are as follows: (1) Desert research requires many disciplines, and although men of science usually prefer to talk to specialists in their own discipline, a conference of this type bringing together the various experts dealing with arid zones is valuable and should be repeated every four or five years. (2) In all the branches men of science are still struggling to clarify their ideas; in some of them even commonly accepted definitions and terminology are still lacking. Nevertheless, (3) the biggest hindrance to progress at the present time is the lack of available data in branches where there is common agreement on which data should be assembled, and there are generally accepted techniques for assembling them. This is true particularly for soil and
water studies and also for certain specialized meteo
ological data. The members of the conferen
unanimously accepted the following resolutions:

"This symposium wishes to draw the attention
the Director-General of Unesco to the followi
resolutions:

"1. That interested Governments be invited
strengthen existing research devoted to vario
problems of arid zones at existing national centr
with a view to (*a*) encouraging fundamental researc
and (*b*) the eventual creation of national bodies whe
the practical problems of each area can be broug
to a focus and considered as a whole.

"2. That the effort devoted to field surveys, unde
taken to obtain the basic data on the arid zone
should be extended and means provided for increas
training facilities for technical personnel required f
field studies and operations.

"3. The symposium attaches great importance
the exchange of scientists and the sharing of traini
facilities on an international basis.

"4. The symposium appreciates the practical i
terest and support of arid zone research and develo
ment of the United Nations, its Specialised Agenci
and of international non-governmental scienti
organizations, and warmly supports the recon
mendation of the Advisory Committee on Arid Zo
Research that Unesco should initiate steps for t
preparation of a handbook to guide collection
basic data".

The proceedings of the symposium will be pu
lished by the Research Council of Israel with financi
support by Unesco.

S. GOLDSTEIN

THE SCIENCE OF DOMESTIC HEATING*

THE subject of domestic heating is of particul
interest at the present time in Great Brita
when the quantity of coal for use in homes may w
have to be reduced as a result of both the eve
increasing demand for coal to satisfy the expandi
power requirements of industry and the urge
economic need to export more coal.

Coal must continue to be the principal domest
fuel in Britain for many years to come, the supp
of alternative fuels being totally inadequate for th
purpose, so that there is every incentive to impro
heating methods and appliances with the view
obtaining more heat and comfort from less co
Furthermore, the greater scarcity of coal and its risi
cost, together with an advance of scientific techniqu
and equipment, have given an added impetus to
more scientific approach to the problem duri
recent years.

The chimney fireplace was first introduced in
England during Norman times and was the beginni
of the familiar open fire of to-day. The early chimne
were large and troublesome; but their size was reduc
only slowly, and it was not until Rumford suggest
a narrowing of the throat of the fire, to reduce roo
draughts and to combat down-draught, that an
marked improvement occurred. A further restrictio
of the throat, with consequent additional advanta
followed upon the introduction of cast iron as

Institution on May 16 by Mr. J. S. Hales, of the British Coal Utilisat
Research Association.

naterial of fireplace construction; but this advance vas lost later when the tile surround became popular nd precluded the use of proper throat control. Cold lraughts increased again, furnishings and clothing ecame lighter, and comfort decreased once more.

It is not always appreciated that, of the heat vailable in coal burned in an ordinary stool-bottom rate in a tile surround, only some 20–25 per cent is mitted as useful heat in the form of radiation. Of he remaining heat, up to 20 per cent passes into the rickwork of the fireplace, and the rest is lost in the lue gases, which include smoke, and in any unburned uel in the ashes. If the chimney is on an inside wall, proportion of the heat lost into the brickwork and n the flue gases may be regained, but the amount is mall because of the low temperature of the flue ases, caused by their admixture with excessive air lrawn into the unrestricted throat of the fire. Attempts have been made, from the seventeenth entury onwards, to make better use of the heat vhich passes into the brickwork of an ordinary open ire, usually by the design of so-called 'convector' ires, in which the fire is partially enclosed within a netal casing. Air circulates through the annulus so ormed, and is heated before re-entering the room. Modern types of convector fire are continuously urning and incorporate underfloor air-control for he rapid revival of 'dead' fires.

Although comparatively inefficient, the open coal ire has the redeeming feature of attractiveness, which s doubtless the principal reason for its retention in omes. To be fully acceptable, however, the open ire must provide an optimum degree of comfort ombined with an economical use of coal.

Comfort may best be defined as the simulation ndoors of the outdoor conditions on a calm, sunny lay in spring—namely, a source of radiation, a noderate air temperature, no excessive air movement nd a reasonable humidity of the air. The economical ttainment of this degree of comfort demands that reater attention be paid to existing methods of ouse-building. A source of radiant heat alone cannot ive the desired room air temperature, while purely onvection heating, which tends to require the mainenance of high air temperatures, leads to a high heat oss and consequent heavy fuel consumption in the ast majority of present-day British houses. This eat loss can only be reduced by careful insulation f walls, ceilings and windows, and by the exclusion f unnecessary draughts. Unfortunately, satisfactory nsulation is impossible in most existing houses, so hat a compromise between solely radiant and purely onvective heating methods needs to be effected.

Such compromises have been proposed for as long s two hundred years, for the *cheminée de Nancy* was n effect an open fire which provided convection eating also. Modern appliances still seek to provide adiant and convective heating, and also to reduce he air flow up the chimney to the acceptable figure f about 2,500 cu. ft./h. for average rooms and ccupancy.

The many earlier proposals for better house-heating nay have been neglected because of a lack of proper esting equipment and facilities. These difficulties re now being removed, however, and in modern esearch into methods of domestic heating use is made f such instruments as the integrating radiometer, the ontinuous-recording balance, and the recording nemometer for the simultaneous measurement of the adiation, rate of fuel consumption and air flow, espectively.

The outstanding problem of domestic fires, and one which will remain as long as coal is the chief fuel, is that of reducing or eliminating smoke emission. From the time when coal was first used as a fuel, suggestions have been made for reducing smoke, many of which require the smoke to pass through red hot cinders before its escape. Devices of this kind undoubtedly reduce smoke, but are difficult to develop as a controllable home appliance. Nevertheless, the attack on smoke has received added impetus from the recent development of precise measuring equipment, such as the thermal precipitator which measures the rate of deposition of tar or soot from flue gases.

The use of instruments of this type and those mentioned earlier, together with the application of modern techniques, should lead to a more rapid improvement in our methods of domestic heating which will remove many of the current criticisms to which we are subjected.

BRITISH COLONIAL TERRITORIES, 1951–52

THE survey "The Colonial Territories 1951–52"*, which includes the usual chapter on research and surveys, again precedes the annual report on Colonial research and provides the essential background against which the recently published "Return of Schemes" made under the Colonial Development and Welfare Acts 1951–52 (see p. 311), and the annual report, "Colonial Research, 1951–52", still to appear, should be appraised. Considerable emphasis is again laid, in the general survey forming Part 1, on political developments, notably the new policy in Malaya, and the problems connected with closer association in Central Africa and with the coming into force of the new Nigerian constitution; but, on balance, the main emphasis in the survey for this year is on economic matters. Financial stringency, for example, and the need to husband funds available for research schemes under the Colonial Development and Welfare Acts, have led to a marked decline in the number and size of research schemes made during the year; but some £1,231,000 was disbursed on such schemes during the year.

Recommendations by Colonial Governments for inclusion in the Colonial Research Service of more than sixty specialist and research posts in departments of agriculture and in veterinary services have been approved; some twenty new appointments were made on Colonial Research Service terms, and fifteen research studentships awarded. Nevertheless, there were still 988 vacancies in the Colonial Service in spite of 1,396 appointments during the year, and, of these vacancies, 281 were in the educational service, mainly for teachers of scientific and technical subjects and for primary teachers. Only 141 civil engineers and 68 mechanical engineers were recruited as against 169 and 70, respectively, during 1950, but 169 medical practitioners were recruited as against 131 for the previous year. The planned expansion of the Colonial Geological Surveys is now almost complete, with an overseas staff of 180, compared with 58 in 1947. In this field valuable help has also been given by United States and Canadian geologists, chemists and mining engineers under a scheme of the Economic Co-operation Administration, and, besides an increase in the total area geologically mapped during the year, continued progress is reported in the investigation of mineral deposits as well as in the discovery of water supplies. The growing interest of the universities in Colonial geology is also proving of practical value. A party of field surveyors, including three Americans recruited by Economic Co-operation Administration, has reconnoitred by geodetic triangulation from eastern Uganda (near Mount Elgon) down the east side of Lake Victoria to Tanganyika and also measured a base near Kisumu. Geodetic triangulation continued in Basutoland, and the Royal Air Force maintained its air-photography programme in Central and East Africa.

---

* Colonial Office. The Colonial Territories, 1951–52. (Cmd 8553.) Pp. x+140. (London: H.M.S.O., 1952.) 4s. 6d. net.

In Zanzibar the work of the team investigating the disease of cloves which threatened the industry with extinction is showing fruitful results. It is now confirmed that the death of young clove trees and the 'die-back' of older clove trees is caused by a parasitic fungus, and there is evidence that 'sudden-death' disease is caused by another fungus. It is expected that methods of control will eventually remove the threat to the economy of the territory, and during these investigations the team also determined the cause of a disease of coconuts. Work with systemic insecticides at the West African Cocoa Research Institute promises to provide a useful adjunct to the method of controlling the 'swollen-shoot' virus disease by cutting out diseased trees.

The survey gives some figures which should be kept in mind in considering the expenditure of £14 million during the year from Colonial Development and Welfare Funds. During the year the dollar surplus of the Colonial territories was 455 millions, 330 millions of which accrued during the first half-year. Development plans adopted during the year include the £75 million plan for the Gold Coast, which does not include the Volta River project, the publicly owned parts of which are estimated to cost a further £65 million with an expenditure by private enterprise of £40 million on the aluminium industry. In the Gold Coast plan, which is to receive £3 million from Colonial Development and Welfare Funds, some £48 million coming from local resources, 17 per cent is to be applied directly to increasing productive capacity in agriculture and industry, 35 per cent to communications and 33 per cent to social services. The revised plan of the Kenya Government for the ten years ending in 1955 contemplates expenditure of £35 million compared with the previously approved £20 million, and here also emphasis is placed on measures designed to improve the agricultural industry. Development plans approved up to March 31, 1952, totalled £456 million, against which £78 million was to come from Colonial Development and Welfare Funds.

Special attention has been given to the problems of mechanization of agriculture in Colonial territories, and the plague of the desert locust (*Schistocerca gregaria*) is being energetically combated by modern mechanized methods in Somaliland Protectorate, Aden Protectorate and Kenya, which is the main danger area; and to co-ordinate such campaigns with those of other countries, a Technical Advisory Committee on Desert Locust Control has been set up to advise the United Nations Food and Agriculture Organization. The urgency of developing the livestock industry has focused attention on the best methods of cattle breeding; a survey of cattle-breeding policy and research was undertaken in the African territories during 1951, and the report is now under consideration. There are now fifty fisheries officers serving or in training, and a feature of the year has been the promising results obtained in fish-farming in the West Indies and in East and West Africa. Supplies to the Colonial territories were adversely affected during the year by world shortages, particularly of iron and steel semi-manufactures, non-ferrous metals and chemicals which contain sulphur. United Kingdom exports of semi-manufactured steel to Colonial territories could not be maintained at the 1950 level.

With regard to education, the survey reports that almost all the buildings in the first programme of the University College of the West Indies will be in use during this year; at University College, Ibadan, in Nigeria, three halls of residence, the science laboratories, arts block and administration building wil be occupied in October this year, and the Nigerian Government has granted £1·5 million for building a new teaching hospital. Courses began last January at the two new colleges of arts, science and technology to be known respectively as the Kumasi College o Technology and the Nigerian College of Technology while work has started on the new buildings of the Royal Technical College, Nairobi, which will serve all the British East African territories. Studies o educational policy and practice in West and in East and Central Africa were initiated, and the findings o the two missions are to be discussed at a conference later this year. An accelerated Development Plan for Education in the Gold Coast was published during the year, and extra-mural departments have been firmly established at the University College of the West Indies and at Ibadan. To meet the need for trained teachers while training institutions are being built up in Malaya, the Malayan Teachers' Training College, at Kirkby, near Liverpool, was opened as a short-term project. Besides the 3,417 students at the Colonial universities and university colleges, there were more than five thousand Colonial students in Britain.

In the health field, the Medical Departments of the African territories are now up to establishment fo medical practitioners, except for a few officers with special experience or qualifications such as pathologists, but in Malaya many vacancies remain. The training of medical auxiliaries is receiving high priority, and the many schools for training locally pharmacists, laboratory assistants, radiographers and physiotherapists are working to capacity. It is hoped that the rural health centres which are being developed will soon be playing as important a part in the life o rural communities as does a hospital service in urban areas. Tuberculosis is now perhaps the greatest socio-medical problem in the Colonial territories, and effort to tackle this problem have been intensified during the year, including the active exploitation of B.C.G vaccination; but in the absence of specific drugs o rapidly effective preventive measures, success i likely to be slow and costly. In leprosy, however successful treatment by the most modern drugs ha completely changed the outlook, and in this world missionary bodies and voluntary organizations have played a conspicuous part. Malaria remains the most universal menace to health, and its complete eradication has so far proved possible only where favourable conditions exist. Total elimination has been maintained in Cyprus, and in Mauritius the incidence ha become negligible, although *Anopheles gambiae* has no succumbed so readily to the residual spraying technique which was rapidly lethal to the principal carrier, *Anopheles funestus*. Some eight hundred olonial student-nurses are taking general nursing, ental nursing or midwifery courses in the United ingdom.

A chapter on international relations, besides giving picture of the extent of technical co-operation both hrough the Specialized Agencies of the United ations and in other ways, gives a clear account of reat Britain's relations with the Trusteeship Council nd of the reasons which led the United Kingdom to ppose two, and abstain from five, resolutions in the discussion by the Fourth Committee of the General Assembly of the report of the Committee on Information from Non-Self-Governing Territories. This is but a single illustration of the way in which this survey of Colonial territories is an invaluable contribution to the discussion of Colonial affairs in general or to the consideration of Colonial development and welfare schemes, and it forms a very useful guide to the scientific and technical work which is reported more fully elsewhere.

NEWS and VIEWS

araday Society: Prof. J. W. McBain, F.R.S.

THE Faraday Society has elected Prof. John William cBain an honorary life member. Prof. McBain has eld the chairs of physical chemistry in the Univerities of Bristol in Great Britain and Stanford in he United States, and after his retirement from tanford was for a time director of the National hemical Laboratory of India. Prof. McBain's ontributions to colloid science and surface chemistry re well known; he was the first to undertake a omprehensive study of the constitution of soap olutions, and is universally recognized as the disoverer of the ionic micelle and a pioneer of the cience of colloidal electrolytes. In this work he has een ably assisted by his wife, Mrs. M. E. Laing cBain. His experimental verification of Gibbs's dsorption equation, by slicing off a very thin layer rom the surface of a solution, and comparing the oncentration of solute in this layer with that in he bulk solution, stands out as one of the boldest xperimental researches in physical chemistry of the ast quarter of a century. He was awarded the avy Medal of the Royal Society in 1939.

Meteor Train

DR. A. R. HOGG, chief assistant at the Commonealth Observatory, Mount Stromlo, Canberra, rites that a spectacular meteor train was seen uring the course of photometric observations at the ommonwealth Observatory. The train first appeared n May 4 at 19h. 15m. G.M.T. (05h. 15m. E.S.T.) gainst a dark sky. For a few seconds it had the ikeness of a comet's tail, about 5° long. This simlarity soon vanished and within thirty seconds of ormation the train was a straight line. In a further alf-minute the top third of the line apparently bent orthwards a distance of about 2°. Subsequent hanges were more gradual. Fifteen minutes after ormation the train was visible as a faint diffuse orse-shoe-shaped glow centred 2 or 3° higher than he original train. Thirty minutes after the formation he area was searched with a wide-field telescope f 5-in. aperture, but no trace of the train could be een. The angular dimensions were estimated from ketches made at the time, and reference to the ackground of identified stars. This gave the position f the centre of the train as near R.A. 14h. 40m. and ec. 37° S. (1950). If it be assumed the meteor first ppeared at the average height of such objects 100 km.), the train was about 20 km. long and istant 140 km. from the observer on a true bearing f 245°. At this point it would not have been illumnated by direct sunlight. The distortion of the train the first half-minute represented a component of otion at the 80–100 km. level of at least 480 km./hr. moving to the north. From the date of appearance and direction of the train the meteor could have been a member of the Gamma Aquarii shower.

Scintillation of Stars and the Atmosphere

A RECENT issue of the *Irish Astronomical Journal* (1, No. 8; December 1951) contains, among others, a paper on "Scintillation and Atmospheric Seeing", by H. E. Butler, of Dunsink Observatory, which gives an excellent account of the reasons for this phenomenon. The study by means of a photoelectric cell of the most rapid fluctuations present in the light from a star has been carried out at Dunsink. The equipment will record fluctuations in the light intensity at frequencies between 0 and more than 1,000 c./s., and very interesting results are shown graphically on a plate. Besides its astronomical applications, there is also the meteorological significance, because the amount of scintillation at any moment could be a measure of the amount of turbulence that is present at the time in the telescope beam. It has already been shown that considerable changes in the scintillation can occur with changing weather.

Research on the Constitution of Alloys

THE Constitution of Alloys Group of the British Iron and Steel Research Association has recently issued a statement dealing with the principal gaps in current research on alloys constitution and indicating its willingness to encourage and assist such research. The alloys that have been insufficiently studied are as follows: high-temperature materials, and, in particular, higher-melting-point alloys of Groups V and VI, systems containing borides, and ferrous alloys containing silicides; ferrous alloys in general, and, in particular, the binary alloys of iron as a basis for further studies of the complex equilibria involved in ternary and quaternary alloys, and also the relationship between the various carbides in alloy steels; magnesium alloys, their heat treatment, and especially the ternary and more complex alloys; high-tensile brass-type materials and the complex bronzes; and finally, general work on the physics of alloys, especially the crystal structures of intermetallic phases and accurate measurement of lattice spacings. It should be noted that by enumerating this list of topics no implication is intended that other subjects and systems in metallurgical research are of lesser interest or do not merit so much study. The Group would also be glad to know of existing equilibrium diagram work which has not been reported to it, and of projected research programmes involving the constitution of alloys. Those interested should communicate with the Secretary, Constitution of Alloys Group, British Iron and Steel Research Association, 11 Park Lane, London, W.1.

Fluorescent Lighting in Museums

An important article in the April issue of the *Museums Journal* (reprinted from *Museum*, 5, No. 1, March 1952, by permission of Unesco) by M. J. Genard, of the University of Liège, on "Extreme Ultra-Violet Radiation from Tubular Fluorescent Lamps and its Effect on Museum Lighting", deals with a subject of great interest to all those concerned with the preservation of objects exposed to artificial light. The paper opens with an admirable survey of the principles involved in fluorescent lighting. Details are then given of the research work of the author and other investigators, from which it appears that radiation from tubular fluorescent lamps in the ultra-violet zone of the spectrum between 310 and 400 mμ is not more injurious than the corresponding radiation from incandescent lamps or sunlight, as long as the conditions of illumination and atmosphere are identical. On the other hand, it is known that the 254-mμ ultra-violet radiation of mercury causes intense photo-chemical reaction in many materials. It would therefore seem probable that there is a region of the spectrum in this vicinity which is to be regarded as particularly dangerous. Tubular fluorescent lamps emit an ultra-violet radiation extending as far as 280–290 mμ in the short wave-lengths. It is feared that these radiations may accelerate photo-chemical deterioration in view of the very marked deleterious action of the neighbouring zone of the spectrum. Neither sunlight nor the light of incandescent lamps contains ultra-violet elements of such short wave-lengths as those found in the light of fluorescent lamps. It is also established that the continuous radiation, due to the fluorescent powders used in certain types of tube, sometimes extends into these extreme wave-lengths. It is to be feared that these types may be more harmful than the others. The transmission curves of the glass in existing varieties of fluorescent tube differ little one from another. It should, however, be possible to use glass which absorbs all rays below 320 mμ. After a tube has been in use for a thousand or so hours, the extreme ultra-violet radiation is approximately 25 per cent less.

National Central Library: Annual Report for 1950

The thirty-fifth annual report of the executive committee of the National Central Library covers the year ended February 28, 1951 (pp. 35; from the Library, Malet Place, London, W.C.1; 1951). Building operations for the reconstruction of the building in Malet Place commenced in October 1950, and it was expected that the west wing and much of the east wing would be ready for occupation in June 1951. The Treasury grant for the year was increased from £22,500 to £25,000, of which £1,000 was to compensate for the third stage in the discontinuance of the contributions from the Carnegie United Kingdom Trust. These, since 1916, have totalled £293,786, including £84,500 to outlier libraries and £41,499 to regional library systems for the compilation of union catalogues, and the report includes a warm acknowledgment of the value of this generous support. There has been a good response from all types of libraries to the trustees' appeal for increased financial contributions, and such contributions were 39·5 per cent higher than those from similar sources during 1948–49. Issues of books from or through the Library during the year decreased by 2,332 to 94,220; but applications increased to 92,740 from 87,931 during 1949–50, the percentage of applications successfully handled being 65·3 as against 71·49 during 1949–50. Issues to university libraries again increased, by 5 42 per cent, to 13,479, while the calls on university libraries for the more specialized books and periodicals also continue to increase. Issues to outlier libraries increased by 20,271, and other specia libraries lent a total of 1,810 books to meet specia needs: fourteen further libraries were added to the list of outlier libraries during the year. Issues from the Scottish and Irish Central Libraries, however decreased to 12,616 and 11,959 respectively, as compared with 15,397 and 12,493 in 1949–50. A total of 609 libraries co-operating in the regional system and the London Borough libraries inter-lending system lent 170,979 volumes to other libraries within their own system and 24,865 books to libraries in other regional systems or to non-regional libraries through the National Central Library, as compared with 164,152 and 21,423 in the previous year. Books lent through the international lending service rose from 994 (twenty-three countries) during 1949–50 to 1,58 (thirty-eight countries), and books borrowed from 420 (nineteen countries) to 584 (nineteen countries) Less time was spent on cataloguing Russian books and periodicals; but 4,899,620 entries have now been supplied for the national Union Catalogue.

Science in Latin America

Four publications have appeared of late which chronicle contemporary scientific activities in Latin America. Three of them, which form part of the very comprehensive series of lists published by the Unesco Science Co-operation Office for Latin America, are entitled as follows: "Venezuela, Vol. 1" (pp. 131) and "Brazil, Vol. 3" (pp. 230) of the list of "Scientific Institutions and Scientists in Latin America", and "Latin American Contribution to Scientific Progress Chemistry, 1948–49" (pp. 50). The fourth volume published by the Ministry of Education of the Argentine, is a "Compilation of the Bibliographies in the Library of the Faculty of Agronomy and Veterinary Science of the University of Buenos Aires" (pp. 30). The two publications dealing with Brazi and Venezuela follow the familiar pattern adopted for other Latin American countries (see *Nature*, 165, 589 (1950); 166, 1059 (1950); 167, 972 (1951)), and their scope is indicated by their titles. The volume on chemistry is one of a number of reports which it is intended to publish every two years, for the purpose of making known the Latin American contributions to the progress of science; the text, in English, gives abstracts of the work, grouped under topics, and a bibliography of papers. The fourth work, though theoretically restricted to papers and books in the field of agriculture and veterinary science, liberally interprets this restriction to mean any publication in science and engineering with a bearing on the field in question; it is sub-divided by subjects, and within each subject the contents are listed alphabetically by author.

National Institute of Economic and Social Research: Report for 1951

The National Institute of Economic and Social Research, which was founded in 1938 as an independent non-profit-making body, has as its object the propagation of knowledge of the social and economic conditions of contemporary society. In its report for 1951 (pp. 32; from the Institute, 2 Dean Trench Street, Westminster, London, S.W.1; 1951), it is explained that the activities of the Institute are

ow to be directed largely to research into industrial
nd commercial capital, and inquiries have already
een started into the finance of public companies
nd the stock of capital assets. Among previous
search projects now nearing completion are
vestigations into trends in retail trading, con-
umers' expenditure and behaviour during 1920–38,
nd the location of industry. The inquiry into trends
retail trading traces the changing pattern of retail
ading during the past fifty years or so. with par-
cular attention to the development of multiple-shop
nd co-operative retailing. The project dealing with
ocation of industry was undertaken by the Institute
n the invitation of the Board of Trade for the
urpose of investigating the private costs of firms
hich have opened branch manufacturing plants.
n interim report was presented to the Board of
rade in 1950 in which the costs of the branches
ere compared year by year with those of the parent
ctories. On the basis of the work already done, it
hoped to establish the cost of mobility in certain
dustries and to assess the relative importance of
arious location factors in these industries.

fth Plant Breeders' Conference

The fifth Plant Breeders' Conference under the
uspices of the Agricultural Research Council was
eld during July 24–26 at the John Innes Horti-
ltural Institution, Bayfordbury. Prof. K. Mather
nd Dr. E. E. Cheesman represented the Agricultural
esearch Council. Dr. C. D. Darlington was in the
hair. The scope of this year's conference was
idened to include not only members of the British
lant breeding institutions but also representatives
om the National Vegetable Research Station,
otato Genetics Station, East Malling and Long
shton Research Stations, the Scottish Horticultural
esearch Institute, certain university departments
nd commercial seed firms. This enlargement
sulted in a valuable exchange of ideas between
search workers in different fields. The morning
rogrammes were devoted to demonstrations of work
rried out by the four departments of the John
nes Horticultural Institution. In all, there were
irty different demonstrations. The afternoon
ogrammes consisted of papers followed by dis-
ssions. The papers were: "Breeding for Yield",
G. D. H. Bell and R. N. H. Whitehouse; "Variety
esting", by J. C. Haigh; "Reproduction of Stocks",
F. R. Horne; "Aids to Plant Breeding", by
. J. C. Lawrence; "Aims and Methods in Plant
reeding", by D. Lewis. A summary of each paper
nd a full account of the conference will appear in
eredity. The next conference is expected to be
ld at the Plant Breeding Division, Stormont,
orthern Ireland, during July 6–7, 1954.

russels Conference on Ultrasonics

The proceedings of the International Conference on
ltrasonics, held in Brussels during June 1951 (see
ature, 168, 106; 1951), have now been published
book form by the Koninklijke Vlaamse Academie
oor Wetenschappen, Letteren en Schone Kunsten van
elgie (Brussels; 225 francs), under the auspices of
hich it took place. Thirty papers, divided into four
ctions, are covered in about three hundred pages:
ropagation in fluids; absorption in electrolytes and
bration potentials; propagation in liquid mixtures
nd suspensions; propagation in liquid helium. The
nference thus dealt with the fundamental aspects
ultrasonics in fluids, in contrast to the international conference in Rome for the previous year, which was concerned mainly with applications in industry and medicine. Many of the papers in the first three sections at the Brussels conference were devoted to the theoretical or practical aspects of ultrasonic absorption considered as viscous or relaxation effects, and some discussion took place on the validity of the supposition that dilatational—as well as shear—viscosity plays a part in these phenomena. In the fourth section, there are a number of papers discussing the various theories which have been put forward to explain the existence of 'second sound' in liquid helium II.

Birmingham Symposium on Analytical Chemistry

Following the International Congress on Analytical Chemistry in Oxford during September 4–9, the Midlands Society for Analytical Chemistry is arranging a symposium on analytical chemistry, to be held in the Chemistry Department of the University of Birmingham, during September 11–12. The main purpose of the symposium is to give those chemists in the Midlands who are unable to attend the Oxford Congress, the opportunity of hearing papers by, and meeting, analytical chemists of international repute. Prof. Fritz Feigl, of Rio de Janeiro, will be the honorary chairman. The programme on the first day will consist mainly of papers concerned with fundamental concepts of analytical chemistry, and the second day will be devoted to original methods. In addition, visitors will have the opportunity of seeing some of the research projects being carried out in the Research School of Analytical Chemistry at Birmingham, which is one of the largest and best equipped in Europe. The registration fee for non-members of the Society is 10*s*. and for members 5*s*. Further details can be obtained from the honorary secretary of the Society, W. T. Edwards, 100 Rymond Road, Birmingham 8.

International Institute of Welding: Meeting in Gothenburg

The annual meeting of the International Institute of Welding will be held this year in Gothenburg during September 7–13. On the first day there will be a meeting of the governing Council of the Institute, and the following four days, September 8–11, will be devoted to meetings of the fifteen technical Commissions composed of representatives appointed by the societies belonging to the Institute. On the morning of September 12 visits will be made to shipyards and other works in Gothenburg, and in the afternoon four papers on "Welding in Shipbuilding" will be given by representatives of France, Great Britain, Sweden and the United States. The official programme will close with a further meeting of the governing council on September 13, after which those taking part will be free to join in a series of works visits in Stockholm, Malmö and other industrial centres, organized by the Swedish member societies of the Institute. Further information and enrolment forms can be obtained from Mr. G. Parsloe, Secretary-General, International Institute of Welding, 2 Buckingham Palace Gardens, London, S.W.1.

Museums and Education: Seminar in New York

A seminar on "Museums and Education", organized by the United Nations Educational, Scientific and Cultural Organization, will be held in Brooklyn during September 14–October 12, under the directorship of Dr. Douglas A. Allan, director of the Royal

Scottish Museum, Edinburgh, with Dr. Hanna T. Rose, of the Brooklyn Museum, New York, as associate director. Senior officers will deal with individual subjects as follows: Dr. Torsten Althin (Tekniska Museet, Stockholm), science museums; Dr. J. Wijenbeek (Municipal Museum, The Hague), art museums; and Dr. F. T. de Souza (Ministry of Education, Rio de Janeiro), educational organization. Forty-five participants representing their respective countries in the United Nations will attend the seminar, together with fifteen expert observers, representing interested parallel or kindred organizations. There will be opportunities for inspecting museum and educational projects as far afield as Washington, D.C. The topics for discussion will include the following: subjects of education in various countries suitable for museum treatment, and the extension of school and college curricula to utilize museum resources for the training of museum and educational staffs for the work under consideration; the varied techniques required for different mental ages; contributions to the development of the handicapped; the initiation of fundamental education in under-developed countries; and the employment of the latest scientific inventions in the more advanced centres.

Lectures on Nuclear Reactors

A course of thirty lectures will be given in the City and Guilds College, University of London, during the 1952–53 session by members of the Atomic Energy Research Establishment (Ministry of Supply), Harwell. The first group of twelve lectures will be concerned with slow-neutron natural uranium reactors, concluding with a detailed description of the large pile at Harwell (BEPO). Another group of six lectures will deal with particular aspects of reactors of various types. Information will be given on the various possible systems, and the problems involved in metallurgy, chemistry, engineering, heat transfer and physics, will be discussed. One lecture on health physics will be included. A group of three specialized courses will include five lectures for mathematicians on more advanced slow- and fast-neutron theory; five lectures for engineers on heat transfer and reactor design; and a lecture for physicists on the experimental use of a reactor, followed by the opportunity to take part in experiments involving neutron diffusion and the measurement of a neutron flux. At the end of the course it is hoped to arrange a visit to inspect the Harwell piles and give an opportunity for informal discussion with the various lecturers. All the lectures are free to students of the City and Guilds College and London intercollegiate students; for others a fee of ten guineas, to be paid to the City and Guilds College, London, S.W.7, will be charged for the whole course, with reductions for those who wish to attend only a selected part.

British Institution of Radio Engineers: Awards for 1951

The British Institution of Radio Engineers has announced the following awards for 1951: *Clerk Maxwell Premium* (for the most outstanding paper published in the Institution's *Journal* during the year), to Dr. H. Paul Williams (formerly of A. C. Cossor, Ltd., and now with Fairey Aviation Co.) for his paper on "Subterranean Communication by Electric Waves"; *Heinrich Hertz Premium*, to R. E. Spencer (E.M.I. Engineering Development, Ltd.) for his paper on "The Detection of Pulse Signals near the Noise Threshold"; *Louis Sterling Premium*, t Emlyn Jones (Mullard Research Laboratory) for hi paper on "Scanning and E.H.T. Circuits for Wide Angle Picture Tubes"; *Leslie McMichael Premium* to R. G. Kitchenn (formerly of the Local Lines an Wire Broadcasting Branch of the Engineer-in-Chief' Office, General Post Office) for his paper on "A 8-Channel Transmitter for an Experimental Carrie Wire-Broadcasting System"; *Brabazon Premium* (fo the most outstanding contribution to the Institution' *Proceedings* on radio or electronic aids to aircraf safety), to G. E. Roberts (Decca Navigator Co Ltd.) for his paper on "The Design and Developmen of the Decca Flight Log"; *Marconi Premium*, t E. G. Rowe (Brimar Valve Division, Standar Telephones and Cables, Ltd.) for his paper on "Th Technique of Trustworthy Valves"; *President' Prize* (awarded to the most successful candidate i the Graduateship examination) and the *Electroni Measurements Prize* (awarded to the most outstanding candidate in Part IV, electronic measurements, of the Graduateship examination), to G. R Beswick (Birmetals, Ltd., Quinton, Birmingham) *Mountbatten Medal* (awarded to the most successfu candidate who passed the Graduateship examinatio while serving in the Armed Forces), to C. J. Whit (B.B.C., Daventry, and formerly of the R.A.F.).

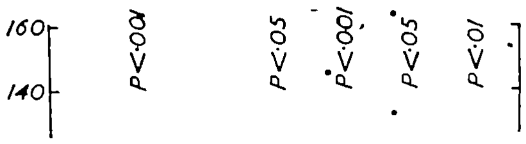
Announcements

Mr. William E. Miller has been nominate president-elect of the British Institution of Radi Engineers for 1952–53. Mr. Miller has been a membe of the Institution for twenty years and was electe a vice-president in 1948, having previously bee chairman of the General Council. He was one of th original signatories to the incorporation of th Institution in 1932.

The first of the Radio Industry Council's premium of 25 guineas for technical writing, to be awarded t authors of technical articles deserving to be commended by the industry, has been won by Mr. J. R Acton, of the Ericsson Research Laboratorie Nottingham, for his article on "The Single-Puls Dekatron", published in the February issue c *Electronic Engineering*. The dekatron is a new typ of gas-filled cold-cathode ray tube now bein developed for use in scalers and computors.

Mr. T. E. Goldup, a director of Mullard, Ltd., ha been appointed chairman of the Board of Governo of the Ministry of Supply School of Electronic Malvern, in succession to Prof. Willis Jackson, professor of electrical engineering, Imperial College c Science and Technology, London. Mr. Goldup, wh has had a wide experience of technical education i the electronics field, has been with the Mullar organization for more than twenty-nine years, an was formerly a member of the research staff c the Signal School, Portsmouth.

Erratum. In the communication entitled "Som Electrical Differences between Healthy and Viru infected Potato Tubers", by C. G. Greenham *et al* which was published in *Nature* of June 7, p. 973, it regretted that the top portion of the illustration incorrect and should be as follows:



SCIENTIFIC CIVIL SERVICE

PROMOTION OF INDIVIDUAL RESEARCH WORKERS

IT is announced that, as in previous years, special posts have again been created to provide for the romotion in the Scientific Civil Service of individual esearch workers of exceptional merit. These promotions, which include for the first time one to the rade of chief scientific officer, are effective from July 1.

Chief Scientific Officer

Mr. S. B. Gates has been at the Royal Aircraft Establishment, Ministry of Supply, since 1915, where e has acquired a reputation as one of the leading uthorities in Great Britain on fundamental problems in aerodynamics. He has been particularly concerned with control problems, and the comparative ease with which the modern high-speed aircraft can be andled by the pilot owes much to his work.

Deputy Chief Scientific Officers

Sir Donald Bailey joined the Experimental Bridging Establishment, now the Military Engineering Experimental Establishment, Ministry of Supply, in 1929 and has been continuously working on design nd development of bridging equipment for the Army. His most spectacular achievement is the ridge which bears his name, which has been found o have outstanding advantages in other fields of ivil engineering.

Dr. F. E. Jones joined the Telecommunications Research Establishment, Ministry of Supply, in 1940 nd played a large part in the development of elecronic circuits used in radar equipment for the R.A.F. He has also played a prominent part in the appliation of radar techniques to the study of weather nd of weather forecasting.

Dr. K. M. Smith, director of the Plant Virus Research Unit, Cambridge, of the Agricultural Research Council, s a noted authority in the field of plant virus research. He has described many new virus diseases of hortiultural and other plants and has investigated their ransmission by insects and other means; he has tudied the causal viruses by filtration and electron microscopy and, more recently, has greatly extended nowledge of the polyhedral diseases of insects. He s the author of a number of books on plant virus iseases.

Dr. R. L. M. Synge, of the Rowett Research nstitute, was jointly responsible with Dr. A. J. P. Martin for the early study and development of partition chromatography as an analytical procedure. He is also known for his structural studies on the ature of gramicidin, and, more recently, for his hemical studies of the nitrogenous compounds in reen leaves and micro-organisms and the influence of degradation of protein in the rumen on its utilizaion by the ruminant animal. He is continuing to develop physicochemical techniques, such as electrophoretic ultra-filtration, for the analysis of substances of biochemical interest.

Senior Principal Scientific Officers

Mr. G. Bradfield joined the National Physical Laboratory in 1949 to initiate work on ultrasonics after experience since 1923 in industry, the Air Ministry and the Telecommunications Research Establishment, Malvern. His earlier work was concerned mainly with the design and development of radio valves and centimetre radar, including responsibility for the design of complex war-time navigational devices. Since 1945 he has been engaged primarily in ultrasonic studies and is now a recognized authority on the subject. He is perhaps best known for the techniques developed for various purposes, such as flaw detection and the determination of elastic constants of crystals of isotropic and anisotropic solids over wide temperature ranges. In these fields the use of barium titanate as a novel piezoelectric material of high coupling has been explored and has yielded much improved devices.

Dr. W. P. K. Findlay, who is officer in charge of the Mycology Section of the Forest Products Research Laboratory, is a graduate of the Imperial College of Science and Technology, London, where he was awarded the Edward Forbes Medal and a Remanet Fellowship. In 1925, on a Fellowship of the Empire Cotton Growing Corporation, he studied first at Cambridge and later in Trinidad. In 1927 he joined the Forest Products Research Laboratory and was associated with K. St. G. Cartwright at the beginning of the Laboratory's systematic investigation into fungal decay in timber. As a result the technique of recognition, in the absence of fructification, of the fungi responsible for various kinds of wood rot by growing them in cultures was developed and has led to the establishment of the Wood Destroying Fungi Section in the National Collection of Fungi. He has also undertaken the mycological aspects of comprehensive investigations into the influence of fungal infection on the mechanical properties of wood. Dr. Findlay has been joint honorary secretary of the Biological Council from its inception in 1945 and has also been president of the British Mycological Society.

Mr. A. H. Ford-Moore has served in the Chemical Defence Experimental Establishment of the Ministry of Supply since 1921. He has played a leading part in chemical research into methods of defence against chemical warfare. He is an outstanding experimentalist and well known for his work on the organic chemistry of sulphur and phosphorus.

Dr. M. H. Hey, of the Department of Mineralogy, British Museum (Natural History), is a mineralogist and chemist of outstanding quality. His work on zeolites and his correlation of their properties with their crystal structure, and especially his study of the role of water in their constitution, was done between 1930 and 1937. He has specialized in inorganic microanalysis, and it is due to him that the chemical composition, and therefore the crystal structure and content of the unit cells of many new minerals, have been established. In addition to his chemico-mineralogical work, Dr. Hey has charge of the great collection of meteorites in the Natural History Museum; in this work he has contributed many analyses of new meteorites and has just completed a new catalogue of the collection. He is the author of "An Index of Mineral Species and Varieties arranged Chemically".

Mr. W. R. Lane joined the Chemical Defence Experimental Establishment of the Ministry of Supply in 1929. His work has been mainly concerned with the physics of chemical defence problems, in which field his fundamental studies on the mechanism of the break-up of liquid drops and the formation of aerosols has contributed materially to present-day knowledge. His ingenious microburette for accurately delivering small drops of known size has now become a well-known instrument which is used in laboratories all over the world.

Dr. J. G. Nagelschmidt, of the Safety in Mines Research Establishment, is a mineralogist of international reputation and is now engaged on research into the mineralogical aspects of pneumoconiosis. He has been a pioneer in the application of X-ray diffraction techniques to the study of clay materials, in the application of new mineralogical techniques to the study of dusts responsible for lung disease, and in the application of the electron microscope to the study of clay minerals and dusts. He has developed and is still developing new techniques for the quantitative mineralogical analysis of small dust samples and for the identification of particular mineral particles too small for identification with the optical microscope. He is a member of the Industrial Pulmonary Diseases' Committee of the Medical Research Council and is secretary of the Sub-Committee on Dust.

Dr. H. H. M. Pike joined the staff of the Research Department, Woolwich, now under the Ministry of Supply, in 1932, his early work being concerned with the internal ballistics of guns. More recently he has turned his attention to the study of the phenomena occurring during the detonation of high explosives, and his findings are the basis of civil defence teaching in connexion with the effects of blast on buildings.

Mr. J. S. Preston has been at the National Physical Laboratory for the past twenty-five years and was at first concerned with the development of photometric and radiometric methods of measurement. Through his work a standard design for commercially produced photo-emissive cells for precision photometry has been adopted. Later his attention was attracted to selenium cells, and he undertook investigations into their use in physical photometry; but the wide divergence between the theory and their practical behaviour led to a detailed investigation into the fundamentals of the constitution of rectifying contacts. This in turn was followed by work on the deposition and properties of a wide variety of thin films, and in this connexion the most recent development is the discovery of the technique necessary for the deposition on glass of a transparent electrically conducting metallic film of low resistance; this will have considerable practical value, as an electric current passing through the film will generate sufficient heat to prevent the deposition of moisture. Mr. Preston was the general secretary of the International Commission on Illumination during 1932–49.

Dr. J. Thomlinson joined the Royal Aircraft Establishment, Ministry of Supply, in 1939, where his work has been directed to the problems connected with the landing and take-off of aircraft from ships at sea and from confined spaces on land. He carried out the first known fundamental investigation into the performance of arrester gears used in deck landings of aircraft, and he originated and has since been responsible for the development of the flexible deck system for landing high-speed aircraft.

Mr. C. K. Thornhill entered the Ministry of Supply in 1940 and has been attached to the Armament Research Establishment since 1943. Througho this period he has worked with conspicuous succe on mathematical problems connected with guns an explosions. His contributions to the field of gu erosion were recognized by the United States Gover ment in 1947 by the award of the American Med of Freedom.

Mr. J. H. Whitaker, who joined the Royal Ai craft Establishment, Ministry of Supply, in 1936, a mechanical engineer and has made valuable con tributions in many fields. He became a recogniz authority on aircraft fuel and oil systems during th Second World War and has since been responsib for the development of essential components f guided missiles.

PHYSICAL SOCIETY

ANNUAL GENERAL MEETING

AT the annual general meeting of the Physica Society, held at the Royal Institution on Ma 20, the reports of the Council and of the honorar treasurer and the accounts and balance sheet for 195 were presented and adopted. The officers and Counci for 1952–53 were elected (see *Nature*, June 14, p. 995) At the extraordinary general meeting held immediately prior to the annual general meeting, Profs. Ott Hahn and M. T. von Laue were elected to honorary fellowship of the Society, and certain changes in th articles of association of the Society, which woul make the procedure of election of officers and Counci more democratic, were agreed to be submitted to th Board of Trade for approval.

During 1951, the Council reports, the membershi rose to 2,025 and the activities of the Society agai increased. It is gratifying to note that the decline i recent years in the number of newly elected Fellow has been arrested and that there have been substantial increases in both the studentship and fellowship grades. The work of the Society has been considerably hampered by rising costs of publication an shortage of paper, and the Council has given earnes consideration to the possibility of effecting economie and increasing efficiency. A scheme for introducin a reduced basic subscription for membership of th Society, with separate payment for all publications has received considerable support and it is likely tha some such scheme will be adopted for operation i 1953. Closer collaboration has been effected betwee the Society and the Institute of Physics, and member now receive notice of meetings of the Institute, whic they are invited to attend. They may also obtai one of the Institute's two journals at a reduce subscription-rate.

In addition to nine science meetings held in Londo during the year, a two-day meeting was held a University College, Southampton, and three-day meetings at University College, Swansea, and at th Queen's University, Belfast. In April a conversazion for members and their friends was held in the room of the Royal Society and the Royal Geographica Society. The seventeenth Thomas Young Oratio was delivered by Prof. W. D. Wright, who spoke o modern problems in colorimetry; the thirty-fift Guthrie Lecture by Prof. N. F. Mott, on the mechanical properties of solids; and the 1951 Parson Memorial Lecture by Mr. F. Twyman, on Sir Charle Parsons and optical engineering. Sir Thomas Merto was the recipient of the sixth Holweck Medal of the Société Française de Physique and the Holweck Prize of the Physical Society; the presentation took place on May 15 at the Salons de l'Université à la Sorbonne, Paris, when Sir Thomas delivered the Holweck Discourse on the subject of new methods of making diffraction gratings. Sir George Simpson received the sixth Charles Chree Medal and for his address gave reminiscences of fifty years work in geomagnetism and geophysics. The twenty-eighth Duddell Medal was presented to Dr. A. B. Wood, who gave an account of his work on underwater acoustics, and the seventh Charles Vernon Boys Prize to Dr. J. H. E. Griffiths, who discussed ferro-magnetic resonance.

Details of the activities of the four Groups of the Society, the Colour, Optical, Low Temperature and Acoustics Groups, together with a list of the numerous bodies on which the Society is represented, are given n the annual report. In addition to science meetings, the Low Temperature Group held two major conferences—the Oxford Conference on Low Temperatures, and the Eighth International Congress of Refrigeration, in London. The Acoustics Group took an active part in the establishment of *Acustica*, and also in the general arrangements of the Acoustics Division of the Building Research Congress held in London during September.

The honorary treasurer again directs attention to the dependence of the financial structure of the Society on the success of the annual exhibition, which, although it had a record attendance and was of high standard, nevertheless resulted in a much smaller financial benefit to the Society than in the previous year. Thus the Society only just paid its way during 1951, and the future outlook depends very largely on the extent to which costs continue to rise. However, with the continued support of its members and with the suggested modifications in the form of subscriptions, it is hoped that the financial position of the Society may be made secure without curtailment of publications or activities.

MARINE BIOLOGY IN SCOTLAND

REPORT FOR 1950–51

THE annual report and collected reprints (Nos. 57–87) of the Scottish Marine Biological Association for the year 1950–51* have recently been pubished. A study of this volume leaves no doubt that the Association's Millport Laboratory is working most successfully and at very high pressure. The scientific staff now numbers nine (excluding the Director), and their researches cover many fields, including plankton nvestigations, a re-survey of the fauna of the Clyde Sea Area, the life-history of barnacles, the factors governing barnacle settlement and their relationship with those governing other settling organisms, the operation of fishing trawls, oyster culture and marine algology. Of special interest and importance is the initiation of experiments in underwater television, for which a special grant has been obtained from the development fund of the Association. A new device for measuring the depth at which gear is working in the sea is also being developed. Already this apparatus can be used to a depth of 200 m. with an accuracy of ± 2 per cent in continuous readings on deck.

To improve facilities at the Station, a new two-story building with a reinforced concrete seawater storage tank on its roof is being built. The masonry of some extra research rooms, and a new workshop and store are mainly completed. Reconstruction of the aquarium is about to be put in hand. Certain administrative changes have also been made by which the Director of the Station acts also as Secretary to the Council—an arrangement that should bring about increased efficiency and smoother running of the whole establishment.

The Oceanographical Laboratory at Leith now comes under the administration of the Association, a special sub-committee of which has been nominated to advise on matters of scientific policy. The programme of research follows two main lines—plankton recorder surveys and investigations into the relationship between the herring and its environment during the Scottish summer fishery at Fraserburgh. During the year some thirty thousand miles of recorder sampling was carried out, the analysis of which must alone be a huge undertaking.

Until lately the Leith laboratory was administered by Hull University College and its reports published as *Hull Bulletins of Marine Ecology*. It is intended to continue their publication in the same format but under a suitably modified title such as *Bulletins of Marine Ecology*.

The Laboratory's present accommodation at Leith and Edinburgh is unsatisfactory and inadequate; but negotiations are now proceeding for the purchase of a property in Edinburgh which, when converted and equipped, will be more suitable.

---

COLONIAL DEVELOPMENT AND WELFARE

DETAILS OF SCHEMES FOR THE YEAR 1951–52

THE schemes detailed in the latest return made under the Colonial Development and Welfare Acts, covering the period April 1, 1951–March 31, 1952*, bring the total commitments for development and welfare schemes under the Acts to £83,983,947, of which £16,038,184 is for the year in question, and for research schemes to £10,745,100, of which £868,851 is for the year ended March 31, 1952. Of this, £373,826 is for agriculture, £136,803 for medicine, £109,804 for social science, £70,575 for tsetse and trypanosomiasis research, £42,778 for insecticides research, £42,045 for fisheries research, £38,050 for locust control and £9,100 for products research. There are no grants for research fellowships, and only £1,420 for economic research.

Of the actual research schemes, the largest are £97,220 for the establishment of the West African Institute of Social and Economic Research, covering capital and recurrent expenditure during July 1, 1951–March 31, 1956, £70,600 as supplementary provision for four and a half years for the establishment of a West African Rice Research Station at Rokupr, Sierra Leone, and £95,000 for the establishment of a Veterinary Research Laboratory and ancillary facilities in the Federation of Malaya. Pilot schemes for the reclamation of tsetse-infested land in Kenya, Uganda and Tanganyika are allotted £70,000 over four years, and £38,000 over four and a half years is granted for the establishment of a Fisheries Research Unit at the University of Hong Kong. Other grants include £34,500, also over four and a half years, for research into the incidence of maize rust in West Africa, £31,500 (over the period January 1, 1952–March 31, 1956) for physiological and biochemical research at Makerere College, Uganda, £34,000 for the establishment of a training centre for ecologists selected for work in Colonial territories, £28,750 for the Anti-Locust Research Centre, and a supplementary £26,620 for the East African Agriculture and Forestry Research Organization for the year ending December 31, 1952.

---

* Colonial Development and Welfare Acts. Return of Schemes made under the Colonial Development and Welfare Acts by the Secretary of State for the Colonies with the Concurrence of the Treasury in the period from 1st April, 1951, to 31st March, 1952. (Cmd. 211.) Pp. 44. (London: H.M.S.O., 1952.) 1s. 6d. net.

The only other grants exceeding £20,000 are: £25,000 for hiring and equipping aircraft for disseminating insecticides in East Africa, £23,000 for further research over four and a half years by Dr. C. A. Walton into relapsing fever in East Africa, £24,403 (supplementary) for the Nutrition Field Station, Fajara, Gambia, £22,083 over four years for re-establishment of the Herbarium at Sandakan, North Borneo, and appointment of a botanist, and £21,000 over three years for the Ecological Land Use Survey, British Honduras. Reference should also be made to the grants of £19,300 for investigation, over five years, of seismic activity in the Windward and Leeward Islands, £17,500 to extend clove research at Zanzibar until August 31, 1953, £15,400 for experiments in East Africa on the dissemination of insecticides from fixed-wing aircraft, and £14,000 for the establishment of a Colonial pool of plant pathologists at the Commonwealth Mycological Institute.

Grants of particular scientific interest for development and welfare schemes, apart from those for scholarship training schemes and the like, include £31,000 for the establishment of an Applied Nutrition Unit at the London School of Hygiene and Tropical Medicine, £150,000 for a Technical College at Nairobi, a further £202,500 for Makerere College, £130,000 for tsetse and trypanosomiasis reclamation in East Africa, £55,300 for the Geological Survey of Somaliland Protectorate, £21,911 for a survey of timber resources in Northern Rhodesia, £9,283 for the extension of the Government Veterinary Research Station, Mazabuka, £52,500 for the Geological Surveys Department of Nyasaland, and £150,000 for the comprehensive survey of the Shire Valley project. A further grant of £52,234 is to University College, Ibadan, Nigeria, and £87,700 for the development of medical and health services in Gambia, while of £6,784,700 for the revised Ten-Year Development Plan for Nigeria, £1,049,832 is for agriculture, £853,053 for technical education, £154,674 for forestry, £395,899 for leprosy control, £1,587,861 for medical and health, and £223,261 for veterinary services. £43,163 is granted for animal husbandry in Sierra Leone, £30,000 for agricultural development in Basutoland, £51,474 for anti-malarial works in Mauritius, £200,000 to the University of Hong Kong, £42,706 for meteorological services in South-East Asia, £55,000 for the Eastern Caribbean Farm Institute, £58,337 for meteorological services in the West Indies, £25,867 for cocoa development in British Guiana, and various sums totalling £311,050 to the University College of the West Indies and its teaching hospital. Grants for road development schemes, rural water supplies, the establishment of local broadcasting services and the like figure prominently among the remainder.

REACTIONS OF PHENYL RADICALS IN SOLUTION AND IN THE GASEOUS PHASE

By M. T. JAQUISS and DR. M. SZWARC
Dept. of Chemistry, University of Manchester

THE reactions of phenyl radicals in solution have been extensively investigated by many workers. A comprehensive summary of these studies has been presented in a monograph by Waters[1]. It appears that phenyl radicals react differently with aliphatic and with aromatic solvents. With the former they seem to undergo an atom transfer reaction; for example:

$$n-C_6H_{14} + Ph\cdot \rightarrow C_6H_{13}\cdot + Ph.H.$$
$$CCl_4 + Ph\cdot \rightarrow CCl_3. + Ph.Cl,$$

while the reactions with aromatic solvents lead to the formation of substitution products. Waters[2] interpreted the course of this substitution reaction by the equation

$$Ph\cdot + C_6H_5X \rightarrow Ph.C_6H_4.X + H. \qquad (1)$$

It is particularly interesting to note that the reaction of phenyl radicals with toluene leads to the formation of the isomeric methyl-diphenyls $CH_3.C_6H_4.C_6H_5$, and that dibenzyl was never detected among the products of the reaction[3]. This observation seems to exclude the alternative interpretation of the reaction, namely,

$$Ph\cdot + C_6H_5.CH_3 \rightarrow Ph.H + \cdot C_6H_4.CH_3 \qquad (2)$$
$$Ph\cdot + \cdot C_6H_4.CH_3 \rightarrow Ph.C_6H_4.CH_3, \qquad (3)$$

since the inequality:

$$C_6H_5.CH_2{-}H \text{ dissociation energy} < CH_3.C_6H_4{-}H \text{ dissociation energy}$$

requires that phenyl radicals should abstract preferentially the hydrogen atom from the methyl group rather than from the benzene ring. Such a reaction, however, would lead to the formation of benzyl radicals:

$$C_6H_5.CH_3 + Ph\cdot \rightarrow C_6H_5.CH_2\cdot + Ph.H, \qquad (4)$$

and thus dibenzyl or diphenyl-methane would be expected as products of the reactions, contrary to the observations.

This peculiar behaviour of phenyl radicals induced us to investigate their reactions in the gaseous phase. Several sources of phenyl radicals were explored by using pyrolytic methods. We found that iodo-benzene, bromo-benzene, mercury-diphenyl, benzyl-benzoate, benzoyl-bromide and benzil generate phenyl radicals in our experimental arrangement, whereas benzo-phenone and azo-benzene required for their decomposition temperatures higher than our experimental conditions permitted. All experiments were carried out in a flow system, described in previous communications[4], the total pressure being of the order 10–20 mm. mercury, and the time of contact of the order of half a second.

Iodo-benzene decomposes rapidly at temperatures of about 600° C. The decomposition is complicated by the presence of iodine atoms and molecules, and therefore is not suitable for studying the reactions of phenyl radicals. Neither is it convenient to use romo-benzene as a source of phenyl radicals, since e decomposition requires rather high temperatures 00–900° C.) and consequently is complicated by the onsiderable amount of products formed by the ecomposition of toluene used as a carrier gas.

The decomposition of benzyl-benzoate (studied in ur laboratories by Mr. J. W. Taylor) seems to take lace according to the expression :

$$Ph.CO.O.CH_2.Ph \rightarrow Ph.CO_2 + Ph.CH_2\cdot, \qquad (5)$$

ollowed by the rapid reaction

$$Ph.CO_2 \rightarrow Ph\cdot + CO_2.$$

the presence of toluene, phenyl radicals react ccording to (4), producing benzyl radicals :

$$C_6H_5.CH_3 + Ph\cdot \rightarrow C_6H_5.CH_2\cdot + Ph.H, \qquad (4)$$

nd the dimerization of the latter yields dibenzyl. he experimental results are given in Table 1, which hows that two benzyl radicals, that is, one molecule f dibenzyl, are produced for each molecule of enzyl-benzoate decomposed (or for each molecule of arbon dioxide formed in the pyrolysis). The initial ecomposition (5) accounts for half the amount of ibenzyl collected, whereas the second portion is ndoubtedly produced by reaction (4).

TABLE 1. DIBENZYL SEPARATED FROM BENZYLBENZOATE BY CHROMATOGRAPHIC TECHNIQUE

T °C.	Carbon dioxide (m.mol.)	Dibenzyl (m.mol.)	Ratio of dibenzyl to carbon dioxide
674	0·448	0·407	0·91
666	0·322	0·312	0·97
704	0·481	0·482	1·00
698	0·404	0·389	0·96
691	0·323	0·321	0·99
687	0·298	0·339	1·16 (?)
699	0·430	0·428	1·00
700	0·399	0·425	1·06
697	0·423	0·404	0·95

m.p. 51° C. after a gentle pressing on a porous tile

The decomposition of benzoyl bromide, investi- ated by Ladacki, Leigh and Szwarc[5], appears to be clean-cut reaction proceeding according to the ollowing mechanism :

$$Ph.CO.Br \rightarrow Ph.CO + Br,$$

ollowed by the rapid reaction

$$Ph.CO \rightarrow Ph\cdot + CO.$$

nder conditions prevailing in our experiments, romine atoms react with toluene yielding hydrogen romide and benzyl radicals[6] :

$$C_6H_5.CH_3 + Br \rightarrow C_6H_5.CH_2\cdot + HBr. \qquad (6)$$

owever, the amount of dibenzyl collected in the yrolysis of benzoyl bromide exceeds that anticipated n the basis of reaction (6) only (see Table 2), and his observation indicates that phenyl radicals eacting with toluene produce benzyl radicals. oreover, benzene was detected among the products f the decomposition, and this proves definitely that eaction (4) takes place (we are indebted to Anglo- ranian Oil Co. for their help in analysing toluene for ts benzene content).

Pyrolysis of benzil appears to be the most con- enient source of phenyl radicals. The reaction takes lace according to the expression :

$$Ph.CO.CO.Ph \rightarrow 2Ph.CO,$$

TABLE 2

T °C.	Carbon monoxide (m.mol.)	Dibenzyl (m.mol.)	Melting point	Ratio of dibenzyl to carbon monoxide
662	1·44	1·15	50–51° C.	0·80
662	1·05	0·84	50–51° C.	0·80
617	0·65	0·49	51–52° C.	0·75
638	1·68	1·20	48–50° C.	0·70
657	1·20	0·97	49–50° C.	0·81

followed by the rapid reaction

$$Ph.CO \rightarrow Ph\cdot + CO.$$

Thus, the rate of formation of phenyl radicals can be measured conveniently by the rate of formation of carbon monoxide. The investigation is simplified by the fact that phenyl radicals are the only reactive species produced initially in the system. Dibenzyl was the only non-volatile product produced in the pyrolysis taking place in the presence of toluene, which proves beyond any doubt that phenyl radicals react with toluene according to (4).

$$C_6H_5.CH_3 + Ph\cdot \rightarrow C_6H_5.CH_2\cdot + Ph.H. \qquad (4)$$

The experimental results are given in Table 3. The melting points of the non-volatile products collected indicate that they contain more than 95 per cent of dibenzyl (in this connexion see also Tables 1 and 2). It has been shown that a mixture containing 95 per cent of dibenzyl and 5 per cent of diphenyl melts at 46–47° C.

TABLE 3

* After gentle pressing on porous tile

We conclude, therefore, that phenyl radicals reacting with toluene in gaseous phase and at high temperatures abstract hydrogen atoms from methyl groups. On the other hand, the reaction in solution and at room temperature leads to their addition to benzene ring. We suggest tentatively the following explanation for the divergence of the behaviour of phenyl radicals. Phenyl radicals, having one hydrogen atom removed from the ring, might approach sufficiently close to the nucleus of an aromatic compound for a relatively strong π—π bond to be formed. To appreciate the strength of such a bond, let us compare $D(CH_3—CH_3)$ with $D(C_6H_5—C_6H_5)$. The C—C dissociation energy of the former is 83 kcal./mole, while we estimate the magnitude of the latter at about 97 kcal./mole. (Investigation of the pyrolysis of bromo-benzene carried out in our laboratories by Mr. D. Williams leads to $D(C_6H_5—Br) \sim 71$ kcal./mole. This value, in conjunction with the relevant thermo-chemical data, leads to $D(C_6H_5—H) \sim 102$ kcal./mole and $D(C_6H_5—C_6H_5) \sim 99$ kcal./mole.) This remarkable increase in the C—C dissociation energy probably measures the strength of the π—π bond in diphenyl[7]. The formation of a π—π bond between a phenyl radical and an aromatic compound leads to a 'hot' complex which contains all the energy of the interaction. Such a 'hot' complex is certainly unstable at the high temperatures and low pressures prevailing in our experiments, and thus it decomposes rapidly. On the other hand, in solution and at room temperatures the excess of energy might be removed by collisions with molecules of solvent, and thus the stabilized complex might survive until a collision with another phenyl radical would lead to the abstraction of hydrogen atom and completion of the reaction.

The fact that the addition reaction prevails at room temperature indicates that its activation energy is probably lower than that of the hydrogen abstraction reaction. Indeed, the analogy with the corresponding reaction of methyl radicals[7] might suggest an activation energy of the order of 8 kcal./mole for reaction (4). [March 20.

ARCTIC AEROBIOLOGY

FUNGI AND BACTERIA, ETC., CAUGHT IN THE AIR DURING FLIGHTS OVER THE GEOGRAPHICAL NORTH POLE

By Prof. NICHOLAS POLUNIN* and Dr C. D. KELLY

McGill University, Montreal, Canada

WHEREAS previous contributions[1] have been concerned with material gathered by Polunin while flying over northern Canada in 1947, the present communication reports upon the result of subsequent flights from central Alaska to the North Pole and back which he made in the following years—in the last instance accompanied by Kelly and S. M. Pady. In the meantime, the work had been adopted as an extra-mural research project by the Defence Research Board of Canada, and it is a pleasure to express gratitude for the all-important governmental assistance in Canada and the United States which has thus been obtained and co-ordinated. These flights were special ones in United States Air Force B-29 (Superfortress) aircraft of the 72nd (Very Long Range) Reconnaissance Squadron operating out of Ladd A.F. Base, Fairbanks, Alaska, and in this connexion our warm thanks are due to the late General Dale V. Gaffney, Colonel Neil D. van Sickle, and Lieut.-Col. Charles F. Overstreet, for the unique facilities afforded and the splendid co-operation of all their officers and men concerned. Thanks and appreciation are also due to the Royal Canadian Air Force for much incidental transportation and hospitality, and to the Defence Research Board in general and Lieut.-Col. G. W. Rowley and Mr. C. P. McNamara of the Arctic Research Section in particular, for their efficient handling of many problems involved. Without such support and the co-operation of many other bodies and individuals, in Washington and Ottawa, Montrea and Alaska, the chance to do this work could scarcely have materialized. There were also the pilots of those long (and in the first case arduous) flights, and the five or six busy navigators and radar observers who made up such a large proportion of the picked and trained crews of fifteen or sixteen—not to mention the almost equally essential ground-staffs o many and various categories, among whom were Major Joseph J. Slack (O.C. Base Weather Detachment), Captain Vaughan (operations officer), the Engineering and Intelligence personnel, and Colone R. R. Stewart (base supply officer).

The first of his polar flights was made by Polunin on September 13–14, 1948. Planning had extended over much of the previous year, with the design and construction of special apparatus for the purpose, and been backed by active work at laboratory techniques by Pady and Kelly[2]. The apparatus, which it is hoped to describe and figure in more detail elsewhere[3] was required for exposure of Petri plates vertically against the unobstructed airstream in front of an aircraft travelling at high speed, with low temperatures outside and possible pressurization inside Essentially it consisted of a steel plate replacing the front large 'Plexiglas' window in the nose, into which a short piece of steel tube was welded in a horizontal position so as to act as a sleeve and lead to an opening in the plate that could be closed by a metal sliding door. A second steel tube, 68 cm. long and blocked off with a handle at the back, was made to slide within the sleeve; its inside diameter was such that it would just take a standard (10 cm diameter) Petri dish which rested against a blocking-off metal plate just behind the front end of this inner tube or cylinder and was held in place by lateral steel clips. In the sleeve was cut a loading-breech with an airtight cover to allow changing of the Petri dishes when the inner tube was withdrawn and the sliding door closed. Loading was accomplished by pressing a sterile, unwrapped, but still covered, Petri 'plate' into position and then removing the cover, after which the breech was quickly closed, the sliding door opened, and the inner tube slid forward and locked in the exposing position in which the Petri plate was held flat against the airstream well ahead of anything else on the plane. In connexion with the construction of this apparatus special thanks are due to Prof. J. S. Foster, of McGill University.

The sticky surface for 'catching' was a thin smear of silicone grease (DC-4-ANC-128-A) on the inside of the base of the Petri dish; this particular grease retains its stickiness through the remarkable temperature-range of − 75° C. to more than 200° C. and appears to be neutral to most biological activity Expert mathematical advice had indicated that we might expect at least 40 per cent of the particles in the atmosphere to penetrate any air-cushion—for example, that might be built up in front of the Petri plate which was already far enough ahead of the nose to avoid its air-cushion—and consequently become stuck on the silicone surface during flight.

Practically throughout the first polar flight and a training and testing preliminary, plates were loaded and exposed for periods of up to ten minutes. Then on return to the laboratory, the silicone surface was 'poured' with melted agar for observation of the fungi and bacteria the growth and development of which were able to proceed when the nutrient covered the surface to which they had become attached. It ad been established that in such circumstances embers of both groups can produce satisfactory olonies[3], the results of such growing and subsequent b-culturing for determination being indicated in e present instance in a table[4]. It should be noted at throughout this article the 'bacterial' colonies are pt to include very occasional (usually single) ones f non-filamentous yeasts which have a very similar ppearance. No Actinomycete was found.

---

* At present on leave of absence as J. S. Guggenheim Memorial Fellow and Research Fellow of Harvard University, Cambridge, Mass.

Whereas the counts are low and indeed often ithin the bounds of possible contamination, their rouping and the working of the controls give condence in their general validity. Thus plates that ere exposed on a wooden post 50 ft. up on a hangar t Ladd A.F. Base throughout the 17 hr. 25 min. of e polar flight gave 100 bacterial and 78 fungal olonies in the case of an agar plate and 350 bacterial nd 72 fungal (of which 60 were filamentous yeasts) the case of a silicone plate which had flies sticking it. Plates exposed for an hour each in the nose f the aeroplane very early in the polar flight gave 13 acterial and 9 fungal colonies in the case of an agar late and 20 bacterial and no fungal colonies in the se of a silicone one; similar exposures for three ours much later in the flight gave 13 bacterial and fungal colonies in the case of an agar plate and 3 bacterial and no fungal colonies in the case of a licone one—which suggests that the air in the lane was not at all heavily loaded and that the licone smear afforded, at least for bacteria, a not es effective method of catching and observing by ubsequent growth than did the very 'general' utrient agar employed. More important were the ading, etc., controls performed very early in, and peated towards the end of, the polar flight. Each nsisted of three 'exposures' of silicone plates, amely: (a) a normal loading, uncovering, re-cover-g, and removing of the plate in the breech without oving the sliding inner tube, (b) the same operation ith, before re-covering and removal of the plate, a ormal sliding of the tube momentarily up to and ack from the unopened front door, and (c) the same (b) except for an opening of the door and further iding forward of the inner tube so that the Petri late was exposed for 2–3 sec. just in front of the rwardmost part of the steel plate before retraction, osing of the door, and re-covering and unloading. ust after take-off for the Pole, (a) and (b) were blank ut (c) gave 22 bacterial and 3 fungal colonies; much ter, on the homeward flight, (a) was blank, (b) gave nly a single bacterial colony, and (c) was blank. he only seriously disconcerting feature about these ntrols is the reading given by (c) after take-off, hich suggests dire need for that scouring of the rward fixed part of the apparatus which was soon be accomplished. It may be expected to have en effected by the time the real exposures were arted many minutes later, although an outlet of ntaminated air due to pressurization may have mplicated this issue.

The main conclusion to be drawn from the results f this very fortuitous sampling as indicated in the able[4] is that, although the air above and around the orth Pole may tend to be practically sterile, it is by o means entirely so. Thus a few bacteria and very ccasional yeasts appear to have been present in a iable condition on this occasion, especially at or ightly above 8,500 ft. in the vicinity of the Pole self. There also appeared to be a slight bacterial eak' not far north of Point Barrow; but unformately, owing to pressurization difficulties, no readings could be taken in this region on the return journey. The relatively high bacterial counts obtained from the earliest exposures made over central Alaska were not borne out by those made farthest south on the return flight, although there is still a significant increase of colonies here (7 on 5 plates exposed for a total of 22 minutes) over the counts made most recently though at the higher altitude of around 18,500 ft. farther north (3 on 9 plates exposed for a total of 31 minutes). The speedy turnover of plates was effected largely to give fresh surfaces, because many rapidly became iced and it was not then realized that 'catching' could nevertheless in all probability still proceed, as supercooled water droplets occur rather than ice crystals in clean air down to −41° C.[5].

Through the kind co-operation of meteorological and monitoring services, we are familiar with the probable sources of the air-masses in which the plates were exposed, on both the northward and homeward-bound flights. There is some suggestion of correlation between the air-mass sources and the biota observed, even if the readings are apt to be patchy. Thus, whereas northward to around 77° N. the exposures were made in air of relatively southern and favourable origin (in which 19 totalling 80 minutes showed 157 colonies in spite of an almost blank 'run' near the middle), north of here the air-mass was of less favourable (northern and largely frozen-up) source, and the next five exposures totalling 24 minutes showed only 2 colonies. The rise thereafter is not accounted for by the computed air-mass sources but may well be due to an extension southward to nearly the 80th parallel in the meridians of the 'pole of inaccessibility' of the very mixed air which tends to circulate around the geographical North Pole, and which on this occasion appears to have had, in part at least, a less unfavourable origin in the Canadian Arctic Archipelago. Thus we have a run of 12 exposures totalling 44 minutes bearing 76 colonies and extending to the actual Pole, followed by 21 totalling 49 minutes and bearing only 18 colonies—quite possibly because, with the exception of the first two which were lower (a 2-minute exposure at 3,000 ft. as the Pole was circled proved entirely blank), they were all exposed at much higher altitudes of mostly more than 18,000 feet. Around 25,000 feet above sea-level over the vicinity of the North Pole, the atmosphere appeared to be entirely sterile. It is quite conceivable that the very low temperatures (at least down to − 48° C.) encountered at these higher latitudes and altitudes may have accounted for a lack of viability in some instances, but it is not now thought that the abiotic radiation effect, if any, is here as great as in temperate regions. Meanwhile it must be emphasized that only the most tentative conclusions should be drawn from these results, which are of a mere preliminary and largely qualitative nature.

The second aerobiological flight over the North Pole took place in March 1949, the object being to carry further such observations as had been made on the previous occasion and to compare winter with more-or-less æstival conditions, while hoping to make a flight under full summer conditions at some later date. Meanwhile Kelly and Pady, particularly, had worked at the apparatus and techniques so that this time it was possible to have the following three systems in operation all together: (1) the qualitative 'artificial hand' for exposing Petri plates in front of the nose of the aircraft as used on the previous occasion, except that, instead of the general silicone smear, two similarly smeared microscope slides which could be removed for separate treatment and examination were stuck with drops of rubber cement side by side on the inside of the bottom of each plate; (2) a General Electric "Electrostatic Bacterial Air-sampler" taking sterile Petri plates and installed in a glass-faced aluminium box connected with the outside atmosphere by 1-in. bore rubber tubes leading from the nose and so arranged, with the inlet pointing forward and the outlet turned aft, as to create a 'Venturi' effect causing a gentle flow of air through the box; and (3) a filter of glass-wool and lens-paper packed in a brass hose coupling of 1-in. inside diameter, similarly connected (in the outlet through a flow-meter) with the outside air by 1-in. hosing. The sampler employs an electrostatic field of some 6,500–7,000 volts and takes two Petri plates at a time, one having its base positively charged and the other negatively, the biota and other particles being precipitated on to their inside surfaces; a constant volume of one cubic foot of air a minute is sampled by being blown over the sterile surface, either a silicone smear or agar medium being used in the dishes. Each filter is made of four disks of glass-wool, each disk being of four thicknesses of the 'wool' as it comes from a fresh roll, cut with a 1½-in. cork-borer and enclosed by lens-paper disks to prevent shearing and to hold the spicules in, this 'stack' being placed in the detachable hose coupling the ends of which are plugged with cotton-wool and then covered with parchment paper caps for sterilization and finally storing after wrapping in a clean paper towel for protection against dirt.[3]

The experience of the previous polar flight had suggested that the air might be virtually sterile, as had winter work by Kelly and Pady over the prairies; on the other hand, we now supposed that catching could proceed even under bad icing conditions; so instead of a large number of short exposures we decided to make most of them last a full hour. On return to the laboratory one of each pair of the nose-exposed slides was microscopically examined for fungi and the other for pollen grains, the area perused in each case being that of a 22 × 50 mm. cover-slip and the mount employed in the latter case being glycerine jelly containing basic fuchsin; the silicone-smeared plates from the electrostatic sampler were 'poured' with agar and the agar ones incubated directly; the glass-wool and lens-paper filter plug was removed with sterile forceps from each coupling and shaken vigorously for ten minutes with 50 c.c. of sterile water, 5-c.c. and 2-c.c. portions being then placed in Petri dishes and melted agar added before incubation at 25° C. and counting after five days.

The results of an abortive mission on March 28 and of a successful polar flight on March 29 and 30 are indicated in another table[4]. All apparatus was well scoured by air before use, the controls and briefer exposures including various loading and other controls of the nature of those practised on the previous occasion with the artificial hand. These were entirely blank as regards pollen grains or allied spores, as were unexposed slides and several exposed for periods of up to seven minutes at various stages of both the 1949 flights, with the exception of a 7-min. exposure made as we were turning in the immediate vicinity of the North Pole, which had on one slide a ragweed or closely allied pollen grain and a smut or allied fungal spore and, on the other, two spores apparently of *Cladosporium*. It is quite possible that these were contaminations, but it is thought that they probabl represent valid observations. Four silicone contro placed at intervals through the flights in the electrostatic sampler and taken out and wrapped aft closing and opening the lid gave an average o 2·25 colonies, whereas nineteen proper exposure gave an average of 5·42 colonies.
